# ELECTROCHEMICAL INDUSTRY

A Monthly Review of Electrochemistry and Electrometallurgy

VOLUME I

From September 1902 to December 1903

NEW YORK:
ELECTROCHEMICAL PUBLISHING CO.

436826
3. 7. 45

# INDEX TO VOLUME I.

## GENERAL ALPHABETICAL INDEX.

*Entries from the Synopsis of Articles in Other Journals are indicated by S. (Synopsis); from the Analysis of Current Electrochemical United States patents by A. (Analysis); from the Digest of Electrochemical United States Patents Prior to July, 1902, by D. (Digest). Illustrated articles are indicated by *.*

### A

ABEL. Obituary ..... 78
Acetone. Deposition of lithium from. Patten and Mott..... 417
——Deposition of zinc from zinc chloride dissolved in acetone. Patten..... 419
— Sodium deposited from sodium iodide dissolved in acetone. Patten and Mott ..... 419
——as a solvent for acetylene. By Hutton ..... 270, 274
ACETYLENE:
——Generation of ..... 476
——Generation of. Dangers of overheating, overgeneration, explosion of mixture with air. By Morcbead.. 479
——and calcium carbide.....116, *125
——Central stations. (S.) ..... 361
——Lamp. Electrolite Gas Lamp Company ..... *194
——Lighting. (S.) ..... 259
——Lighting in mines..... 547
——Dissolved in Acetone. By Hutton. 270, 274
——Black from calcium carbide. Goldschmidt. (S.) ..... 422
Acheson. Biography and portrait ..... *90
Acids. Reduction of unsaturated acids. Marie. (S.) ..... 500
——Conversion of neutral fats or oils into fatty acids and glycerine. Lackersteen. (D.) ..... 598
——Basicity of. Electrolytic determination. Moltkehansen ..... 484
——Alkaline cell (Berthelot). By Reed.. 492
——(See also the different acids.)
Acker Process Company..... *54
Active and inactive state of carbon electrodes in fused electrolytes. Harden ..... 501
Affinity. Chemical affinity at very low temperatures. Moissan and Dewar. (S.) ..... 360
Africa. Metallurgy and chemistry in South Africa ..... 478
Agenic. Reed ..... 128
Air in electrolyte. Electrode effects. Barnes ..... 316
Alcohols. Lithium deposited from. Patten and Mott ..... 419
Alcoholic solutions. Calcium deposited from. Patten ..... 418
Alizarin industry. (S.) ..... 106
Alkali. Electrolytic production of caustic. (See sodium chloride. Electrolysis) ..... 567
——Frasch process ..... 572
——Industry. Kershaw. (S.) .....143, 182
——Action of halogens upon. Foerster and Mueller. (S.) ..... 223
——Caustic as bye-product in the electrolytic manufacture of chromium compounds. Specketer. (A.) ..... 393
——Acid cell. (Berthelot.) By Reed.... 492
——Cyanides from calcium carbide. Frank. Erlwein. (S.) ..... 423
——(See also sodium, potassium, etc.)
Alkaline chlorides. Electrolysis. Foerster and Mueller. (S.) ..... 107
——Sulphides. Electrolysis of. Brochet and Ranson. (S.) ..... 388
ALLOYS:
——Electrolytic preparation. Coehn. (S.) 72
——Electromotive force. Bancroft ..... 320
——Rôle of formation heats of alloys in electrolysis. By Richards ..... 575
——Testing. Sirks, (S.) ..... 144
——Metallic. Sack ..... 429
——Light aluminium alloys. Richards. (S.) ..... 498
——of copper and aluminium. Louquinine Schukareff .....547, 575
——of lead, tin and bismuth. Shepherd. (S.) ..... 184
——of sodium, cathodic formation. Sack. 593
Alloying of metals a factor in electroplating. By Kahlenberg ..... 201
Alternating currents. Electrolytic dissolution of platinum by. Ruer. (S.) 329
——Recording wattmeter. Stanley Instrument Company ..... *398
——Conversion into direct current. Elec
INDEX—ONE
tro-dynamic Company., converter. *339
——Converted into direct, with aluminium electrode. (See Rectifier, Electrolytic.)
——Electrolysis by. Trotter. (S.) 34. Le Blanc ..... *459
——of potassium silicate. Gross. (S.) 390
——of sodium hydroxide. Hambuechen ..... 488
Alumina and carborundum from kaolin. Webber. (A.) ..... 396
ALUMINIUM:
——General ..... 153
——Anode for rectifying alternating currents. (See Rectifier, Electrolytic.)
——Anodes in primary batteries. By Burgess and Hambuechen ..... *167
——as electrical conductor. Kersbaw. (S.) 547
——Electrolytic production. Niagara Falls, 49. Haber (S.) 106. Tagges (A.) *188. Hall, Heroult and Minet processes. By Richards..... *158
——Industry. Pitival. (S.) 256. Kershaw. (S.) .....283, 328
——Metallurgy. By Richards ..... *158
——Gin .....460, 462
——Patent litigation.....336, 519, 522, 560
——Plating upon. By Burgess and Hambuechen ..... 166
——Fischer. (S.) ..... 584
——Plating with. By Burgess and Hambuechen ..... 167
——McDermott. (S.) ..... 585
——Process invention. Haber ..... 384
——Properties of. By Burgess and Hambuechen ..... *165
——as reducing agent. (See Aluminothermics.)
——Separation from iron and nickel. Holland and Bertiaux. (S.)..... 500
——Soldering. By Burgess and Hambuechen ..... 166
——Soldering to iron and steel. (S.)... 504
——Alloys. Effect of atmosphere on. Wilson. (S.) ..... 74
——Light aluminium alloys. Richards. (S.) ..... 498
——and copper alloys. Louquinine and Schukareff .....547, 575
Aluminothermics. 520, 523. By Scholl. *175. By Goldschmidt.....*527, *578
——Weber. (A.) ..... 57
——Pure iron. Houllevigne. (S.)..... 74
Amalgam. Oxidizing metals dissolved in mercury. Baker and Burwell. (A.) 548
——Potentials. Reuter. (S.) ..... 145
Amalgamated cathodes for metal deposition. Reed. (A.) ..... *251
American Aluminium Association ..... 75
American Chemical Society. Cleveland meeting ..... 417
American Electric Improvement Company. Purifying water ..... *228
American Electrochemical Society..74, 89, 113 192, 276, 281, 236, 314, 356, 372, 471, 513 521, 539, 559.
——Election .....260, 327
——Niagara meeting, 1902..... 2, 4, 43, 57
——New York meeting, 1903.....
236, 269, 272, 301, *314
——Niagara meeting, 1903 .....435, 428, 475
American Foundrymen's Association.. . 375
American Institute of Electrical Engineers .....192, 357
——Niagara meeting, 1903..... 344
American Institute of Mining Engineers, 331, 344
——New York meeting, 1903..... 526
American Slate Company. Slate..... 295
American versus German practice..... 44
Amines. Electrolytic manufacture of aromatic amines. Buchner ..... 512
Ammeter. Exteroal shunt. Weston Elec. Inst. Co. ..... *55
——Long scale ammeter for alternating currents. Westinghouse Co. .... *367
——Pocket. Talmont Electric Engineering Co. ..... *515
Ammonia. Manufacture of. Ampere Electrochemical Co. ..... 18
——from calcium cyanide. Frank. (S.). 423
Ampere Electrochemical Co..... 17
Amylamine. Conductivity of solutions in. Kahlenberg and Ruhoff. (S.).... 359
Anaconda Refinery ..... 416
ANALYSIS:
——Apparatus for electrolytic. Perkin.. *414
——Arsenic, electrolytic estimation of minute quantities. Thorpe. (S.).. *546
——Carbides. Gall ..... 542
——Carbon in carbides. By FitzGerald and Loomis ..... 410
——Carboo in ferro-chrome, etc. Seward. *366
——Electrolytic. Arth, (S.) ..... 74
——Hanaman. (S.) ..... 74
——Constant voltage and constant current separations. Bancroft. 315
——of Foodstuffs. Medicus. (S.) ..... 109
——Laboratory for electrolytic. Richard. (S.) ..... 184
——Manganese and lead. Moltkehansen.351, 396
——Manganese separated from iron; aluminium from iron and nickel; zinc from iron. Hollard and Bertiaux. (S.) ..... 500
——of mercury. Glaser. (S.)..... 257
——Quantitative deposition and separation of metals by electrolysis. By Danneel and Nissenson ..... 565
——Quantitative with platinized platinum anodes. By Foerster ..... 448
——Rotating cathode. Shepherd. (S.)... 586
——Standardization of methods. Blount. (S.) ..... 146
Analytical balance. H. Kohlbusch..... *430
Aniline. Reduction from nitrobenzine. Buchner. (A.) ..... 507
Anode. Construction. McDonald. (A.). 190
——Double. Elbs. (S.) ..... 73
——Electrolytic dissolution of soluble anodes. By Johnson ..... 48, 59
——Oval vs, rectangular section for electroplating. By Burgess and Hambuechen ..... *347
——Oval cross section for plating. Starrett. (A.) ..... 469
Anodic formation of insoluble compounds. Isenburg. (S.) .....342, 358
Anthracene. Oxidation of. Moest. (A.) 393
Antimony. Electrolytic preparation. Izart. (S.) ..... 257
——Production from ores. Izart and Thomas. (S.) ..... 283
Araeo-pyknometer. (S.) ..... *145
Argon. Isolation from atmospheric air. Becker. (S.)..... *464
Aromatic compounds. Oxidation of. Sebor. (S.) ..... 360
——Nitrobodies. Reduction of. Elbs and Stohr. (S.) ..... 424
——Nitro-compounds. Reduction of. Buchner. (A.), 507. Haber..... 510
Arsenic. Electrolytic estimation of minute quantities. Thorpe ..... *546
Atmospheric Products Co..... *20
Atomic weights. Empirical formula for Vincent. (S.) ..... 33
Automobile. Charging outfit ..... *363
Azo compounds. Buchner. (A.)..... 505

B

the rare elements.
P. E. Browning..... 472
der Elektrochemie. Vol. VIII. ..... 362
Kalender fur Elektrochemiker. By A. Neuburger, 1903 ..... 363
Lehrbuch der anorganischen Chemie. By H. Erlmann ..... 111
Metallurgical Laboratory Notes. By H. M. Howe ..... 261
—Mineral Industry. Vol. X. ..... 362
—Modern Electrolytic Copper Refining. By T. Uke ..... 594
—The Optical Rotating Power of Organic Substances. By H. Landolt. 111
The Potash Salts. By L. A. Groth.... 193
—Practical Plating and Polishing ..... 227
Radium and other radioactive substances. By W. Hammer ..... 593
Secondary Batteries. By E. T. Wade. 512
—Textbook of Inorganic Chemistry. Holleman. [H. C. Cooper] ..... 362
—Textbook of Organic Chemistry. By A. F. Holleman. [A. J. Walker]. 430
—Transactions American Electrochemical Society ..... 38
Bradley. Biography .....*451, 539
Bradley internal heating patent.....519, 522
Bricks, tiles, manufacturing. Jacobs. (A.) 130
Bromine. Discharges through. Kellner. (S.) ..... 34
Bromoform. Electrolytic production. Kempf. (D.) ..... 598
Browne's nickel-copper process. Haber.. *382
Brush storage battery patent ..... 233
Bunsen Society. Annual meeting 1903, 304, *458, 509, 542, 563
Butter. Purifying. Schwahn. (D.) ..... 598

C

CADMIUM. E. M. F. against cadmium iodide in various solvents. By Kahlenberg ..... 57
—Copper alloys. Denso. (S.) ..... 286
Cadmium cell. Weston's. By Cohen. (S.) ..... 108
—Jaeger. (S.) ..... 286
—as standard. Carhart..... 414
Caesium carbide. Moissan. (S.) ..... 389
Calcium. Deposited from alcoholic solutions. Patten ..... 418
—Furnace process. (S.) ..... 422
—Production of metallic. Borchers and Stockem. (S.) ..... *164
Production in electric furnace. Arndt. (S.) ..... *143
CALCIUM CARBIDE:
—Caro. (S.) ..... 28
—Roberts. (A.) ..... 9.
—Detaching large pieces from ingots in carbide furnaces. Scales. (A.), 251, 288
—Industry in France. (S.)..... 282
—Industry in Italy. Pio. (S.) ..... 70
—Patents. (S.) ..... 106
—Plant of Union Carbide Co..... 22
—Plant in Switzerland. Perkins..... 463
—as raw material for lamp black. Goldschmidt. (S.) ..... 422
—Reactions during formation. Gin. (S.) ..... 32
—Reduction by. Neumann and Kuegelgen. (S) ..... 145
—Refuse treatment. Cox. (A.) ..... 354
—as starting material for alkali cyanides. Frank and Erlwein. (S.) 423
—and acetylene ..... 116, *125
—Muensterberg. (S.) ..... 32
Calcium carbophosphide. Bradley, Read, Jacobs. (A) ..... *189
Calcium cyanide as fertilizer. Frank. (S.) ..... 423
Calomel electrode ..... 487, 488, *537
Calorimetry. Theory and practice of continuous flow. By Barnes ..... 59
Camphidin. Electrolytic production of derivatives of camphoric acid. Tafel. (A.) ..... 354
Canadian Copper Co. ..... 269, 372, 381
Canadian Niagara Falls. (Ca. S.) ..... 186
Canal rays. Chemical effects. Schmidt. (S.) ..... 145
Canadian Smelting Works. Trail ..... *407
Capillary electrometer. Portable. Smith. (S.), 225. Burch. (S.) ..... *185
Carbides. Analysis and test. Gall..... 542
Determining carbon in. By Litz-Gerald and Loomis ..... 416
—Moissan ..... 459
Double carbide of chromium and tungsten. Moissan and Kouznetzow. (S.) ..... 502
—reducing agent. Neumann and Kuegelgen. (S.) ..... 289
—rubidium and caesium. Moissan. (S.) ..... 289
—Silicon. Use in the steel industry. (S.) ..... 283
Carbon cell. Jone. (S.) ..... 586
—Perez. (S.) ..... 586
—Lugo. (S.) ..... 286, 330
—Swinburne ..... 118
Carborundum:
—Combination with chlorine. Bolton. (S.) ..... 284
—Chlorides. Manufacture in electric furnace. Machalske. (A.) ..... 504
—Determination in carbides. By Litz-Gerald and Loomis ..... 410
—Determination in ferro-chrome, etc. Seward ..... *366
—Electricity direct from. Jone. (S.) Lorenz. (S.), 586. Mugdan. (S.), 286, 330. Swinburne ..... 118
—Electrodes. ..... 328
—Active and inactive state in fused electrolytes. Harden. (S.) .. 501
—Baked. Hall. (A.) ..... 30
—Free from silicon, for aluminium manufacture. Hall (A.) ..... 467
Construction. Hargreaves, Stubbs, Kearsley. (A.) ..... *426
—Testings. By FitzGerald..... 57, 58
—(See also Graphite.)
—Monoxide. Dissociation of. Schenck. 503
—Plates. Polishing. By Von Bolton.. 566
—Silicide. (See Carborundum.)
Carbophosphide of calcium. Bradley, Read, Jacobs. (A.) ..... *189
CARBORUNDUM:
—and alumina from kaolin. Weber. (A.) ..... 396
—Articles made from. Tone. (A.).... 97
—Electric conductivity ..... 482
—Manufacture at Niagara ..... *50
—Oxidation of. Acheson ..... 373
—Plant of Carborundum Co ..... *50
—and zinc. Production in electric furnace from siliceous zinc ores. Dorsemagen. (S.), 10[illegible] (A.)... 189
Carboxyl groups. Reduction of. Elbs.... 511
Carnegie's gift for Union Engineering Building ..... 303, 304
Carnot's cycle applied to electrolytic cells. Carhart ..... *326
Caro acid from persulphuric acid. Mugdan. (S.) ..... 502
Cascade Water, Power and Light Co. By McConnon ..... *337
Casting repaired by thermit process. (See Aluminothermics.)
—Improved by anti-piping thermit..... *533
Castner. Biography and portrait ..... *121
—Memorial tablet ..... *156
Castner Electrolytic Alkali Co. ..... *12
Catalysis. By Bodlaender ..... 563
—Discussion of papers of Schenck, Bodenstein and Bodlaender ..... 565
—Reduction of organic compounds by catalysis. By Sabatier ..... 565
—lytic action of metals in electrolytic reduction and oxidation. Coehn.. *509
—of potassium iodide upon hydrogen peroxide. (S.) ..... 258
—phoresis. See Endosmosis.
—saphoric" process of preserving beer. Crotte. (A.) ..... 470
Cathode. Amalgamated for metallic deposition. Reed. (A.) ..... *251
—for deposition of metals. Henry. (A.) ..... 334
—Formation of metallic dust. By Haber ..... 69, 72
—Rôle of cathode material in the reduction of nitrobenzol. By Loeb and Moore ..... 565
—Rotating for metallic deposition. Zimmerman ..... 302, 310, 321
—Rotating for analysis. Shepherd. (S). ..... 586
Cathodic polarization in dilute sulphuric acid. Tafel. (S.) ..... 72
Cathodic reduction. By Weightman ..... 46, 57
Caustic alkali. Sodium chloride in electrolytic caustic alkali. By Townsend ..... 119
—(See also Alkali and Sodium Chloride Electrolysis.)
Cell. Concentration, 2. Carhart..... 9, 58
—Electrolytic for continuous operation. Salom. (A.) ..... *392
Electrolytic and galvanic batteries. By Reed ..... 128
See also Batteries.
Ceric sulphate as oxidizing agent. Foerster ..... 459
Cerium. Electrolytic production. Stockem. (S.) ..... 143
—as oxidizing agent. Moest. (A.).... 393
—Oxides. Electromotive behavior of. Bauer and Glaessner (S.) ..... 425
Chemical industry in Germany ..... 430
Chemical, Metallurgical and Mining Society of South Africa ..... 478
Chemistry and engineering. Ostwald. (S.) ..... 466
Chlorates. Electrolytic production. Cutten. Gall, Gibbs, Franchot, Blumenberg, Hurter, Boettcher, Imhoff, Parker, Gibbs, Vogelsang, (D.), 432
—Bipolar electrode for manufacture of chlorates. Imhoff. (A.) ..... *288
—Electrolytic production, 405. Kershaw. (S.), 71, 106. Lederlin. (A.), 354, 468. Threlfall. (A.) ..... 215
—National Electrolytic Co. ..... 19
—of potassium. Reduction of. Brochet. (S.) ..... 257
—of potassium. Electrolytic reduction of. Tommasi. (S.) ..... 389
Chlorides. Electrolysis of alkaline chlorides. Foerster and Mueller. (S.). 107

——Production of copper, nickel and zinc from. By Koehler .....*540, *568
——of carbon. Manufacture in electric furnace. Machalske. (A.)..... 504
Chlorine. Applications for. (S.) ..... 498
——Combination with carbon. Bolton. (S.) ..... 284
——Generation of Paget. (D.) ..... 598
——Smelting. Swinburne .....404, *412
——(See also Sodium chloride. Electrolysis.)
Chloroform. Electrolytic production. Kempf. (D.) ..... 598
Chromate. Depolarization by potassium chromate. Mueller. (S.) ..... 183
Chromite. Production in 1902 ..... 438
Chromium. Becker process ..... 574
——Free from carbon, manufacture in electric furnace. Borchers. (S.). 143
——Compounds. Electrolytic manufacture. Specketer. (A.) ..... 393
——Double carbide of chromium and tungsten. Moissan and Kouznetzgow. (S.) ..... 502
——Silicides. Lebeau and Figueras. (S.) 501
——Sulphate. Oxidation to chromic acid. 511
Clark cell. Change of volume and e. m. f. with pressure. Ramsey. (S.) .... 257
——Purity of electrolyte. Luther. (S.). 36
——as standard. Carhart ..... 414
Classification of electrochemistry. By Townsend .....237, 377, 520, 535
Cleveland as a center of electrochemical development ..... 168
Colloidal solutions. Theory. Perrin. (S.) ..... 586
——Zirconium. Wedekind ..... 449
Colloids. Zsigmondy. (S.) ..... 108
——and endosmosis. By Bredig ..... 563
Compounds. Electrolytic production of metallic compounds. Burgess and Hambuechen ..... *307
Concentration by electromagnetic means. (See Magnetic Concentration.)
Concentration by electrostatic means. (See Electrostatic Concentration.)
Concentration cell, 2. Carhart..... 9, 58
Concentration. Changes in diaphragm cells for electrolysis of sodium chloride. Townsend, 119. Walker. 317
Concrete tanks. By Browne .....270, *273
Condenser method for measuring electrode voltage. Johnson ..... *455
Conduction. Electrolytic, without electrodes, 317. Grosvenor, 397. Marvin ..... 
——Influence of solvent on electrolytic conduction. Patten. (S.)..... 182
——Metallic and electrolytic ..... 343
——Some phenomenon of electrolytic conduction. By Reed ..... 
Conductivity. Chemical valency, electric conductivity and hardness of metals. Rhodin. (S.) ..... 547
——Electric, of copper. By Addicks..... *580
——Electric, at low temperatures. Dewar, 139. Kunz. (S.) ..... 183
——Electric, of nickel oxides. By Marsh. 122
——Limits of electrolytic. Bonsfield and Lowry. (S.) ..... 183
——Salts of tartaric, malic and succinic acid. By Tower ..... 67
——of solutions in anylamine. Kahlenberg and Ruhoff. (S.)..... 359
Congress. International Electric, 1904..458, 560
——International, for applied chemistry, 236, 394, 570, 572. By H. Dannecl and K. Clemm. *458, 502, 542, 563
Consolidated Lake Superior Co. Ulke process .....*210, 398, 406
Consolidated Storage Batteries Co. Clare battery ..... 294
Converting alternating into direct current. Electro-dynamic Co..... *339
——(See also Rectifier, Electrolytic.)
COPPER:
——Aluminimum alloys. Louquinine and Schukareff .....547, 575
——Cadmium alloys. Denso. (S.) ..... 286
——from chloride solutions. Koehler.*540, *568
——Cuprous ions. Bodlaender. (S.)..... 73
——Electric conductivity. By Addicks... *580
——Leaching and extraction. Hœpfner. (A.) ..... 29
——and nickel. Browne. (A.), 190, *352, *569. Frasch, *252. Guenther (S.), 327,398. Sjoestedt and James. (A.), 393. Thum, Ulke, *210. Vivian.. 208
—— Orford process and Browne process. By Haber..... *381
——Ores in Africa. (S.)..... 388
——Plating with. Dessoli. (S.)..... 105
——Processes of Browne, 190, *382, *569. Carmichael, *274. Dolbear (A.), 98. Hœpfner, *568. Tossisza ..... 98
——Reduction furnace. Barnhart. (A.). 333
——Refining. (See Refining Copper.)
——Salt solutions. Decomposition curves. Heiberg. (S.) ..... 329
——Tensile strength. By Addicks..... *580
——Tubes. Elmore process. (S.)..... 544
Corrosion of metals by electrolysis. Knudson ..... *318
Corundum, artificial ..... 15
Course in electrochemical engineering. By Burpess ..... 9
——in electrochemistry. Tucker. (S.)... 586
——in electrometallurgy in Lehigh University. Richards ..... 419
——in physical chemistry. Loeb and Kimbach. (S.) ..... 74
——in physical chemistry. Smith..... 335
——Chemical, in American and German universities. Haber ..... 350
Cowles Electric Smelting & Aluminum Co. .....494, 560
Cowles, biography and portrait ..... *56
——Pioneer work. By McMillin..... 110
Cowper-Coles Galvanizing Syndicate.... *263
Creatine from tarkosine and cyanamide. Frank. (S.) ..... 423
Crocker-Wheeler Co. Dynamos for electrochemical work ..... *227
Croftan Storage Battery Co. Madigin Battery ..... *293
Crystallization in electric field. Schmidt. (S.) ..... 390
——Electrolytic. Heyl. (S.) ..... 184
Cuba. Mineral resources ..... 478
Curves. Method of curves for determining the best conditions. By Hering ..... *122
Cyan-alkalies from barium cyanide. Frank. (S.) ..... 423
Cyanamide of calcium from calcium carbide and nitrogen. Frank. (S.) 423
——as fertilizer. Frank. (S.) ..... 423
Cyanides. Manufacture. Ampere Electrochemical Co. ..... 17
——Alkali cyanides from calcium carbide. Frank and Erlwein. (S.)..... 423
——of barium from barium carbide and nitrogen. Frank. (S.) ..... 423
——Gold cyanide process. By Walker... 484
——Gold precipitation. By Caldecott and Johnson .....477, 494
——Patents of McPherson. (A.), 393. Davis. (A.) ..... 589
——of potassium. Commercial. (S.)..... 255
——Silver plating baths. Jordis and Stromer. (S.), 465. Powell ....513, 551

Dissociation pressure of soda solutions. Kuester ..... 509
Dissociation theory. Application to medicine and biology. By Bancroft..302, 305
——Discussion on ..... 490
——Ostwald's dilution law. By Liebenow. (S.) ..... 223
——Thermochemistry of. Richards ..... 491
——Wbetham .....403, 410
Double electric layer and absolute potential. Billitzer. (S.) .....107, 546
Dredge for gold. Westinghouse Co..... *262
——Montague ..... 415
——Robinson ..... *562
Drexel Institute ..... 471
Dry cell. Drawbough. (A.) ..... 507
——Fishell and Mottel. (A.) ..... 507
——Kohn. (A.) ..... 254
Dryers. For electroplating purposes. Davis. (S.) ..... 503
——Jeffrey Mfg. Co. ..... *594
Dust. Formation of metallic dust from cathode. By Haber ..... 60,72
Dyes. Electrolytic production ..... 477
——Majert, Blair, Browne, Chaplin, McKenzie, Burton, Salom, Richards, Roepper, Luckow, Collins, Kendall. (D.) ..... 556
——Kendall, Kessler. (D.) ..... 518
——Aromatic amines. Buchner ..... 512
Dynamos. Early for metallurgy. (S.).. 206
——for electrochemical work. C. J. Bogue .....*431, *516
—— Crocker-Wheeler Co. ..... *227
—— Eddy Mfg. Co. ..... *340
—— Elmore. Unipolar. (A.) ..... *428
—— General Electric Co. ..... *296
—— Hanson & Van Winkle Co., Multipolar ..... *100
—— Holtzer-Cabot Co. .....*230, 472

## D

DANIELL cell. Change of e. m. f. with concentration. Richards, 75. Carhart, 178. Cohen and Commelin. (S.) ..... 390
Decomposition curves of copper salt solutions. Heiberg ..... 329
Decomposition voltage. Abnormally low. By Hering ..... 59
——Measurement. Johnson ..... *467
Density. Critical. Traube ..... 488
Dentists' electric furnace. Eimer. (A.), 504. Gerbart. (A.), 131. Hewett and Smith. (A.), 187. Winter. (A.) ..... 333
Deozonization. Spontaneous. Warburg. (S.) ..... 223
Deposition. Quantitative and separation of metals by electrolysis. By Danneel and Nissenson ..... 565
Deposits. Reduction factors for electrolytic deposit. By Hering ..... 240
Dialyzer. Briggs ..... 392
Diamonds. Artificial. Ludwig. (S.).... 144
Diaphragm. Porous. Bucbner. material. 554

### GREETING:

Notwithstanding the great importance [illegible] of electrochemistry have assumed in the United States and the valuable contributions which here have been made to the science and to the art, this vigorous and rapidly expanding branch of national industry has thus far lacked a [illegible] exponent. That a field exists in this country for a journal devoted specifically to the science and application of electrochemistry appears to be clearly indicated by the fact that many others, that no less than six such periodicals are published abroad, namely, three in Germany, two in France and one in England. To supply this vacancy will be the object of ELECTROCHEMICAL INDUSTRY, and it confidently hopes to be accorded in its endeavors the co-operation of all interested in the advancement of the science and the art.

It is the purpose to make this journal an authoritative exponent of electrochemical science and its various applications, and to this end the aid will be secured, so far as possible, of the leading authorities of the world in electrochemistry. In accordance with the fruitful policy of the best class of American technical journalism, the plan of the publication is to cover the field so broadly that its pages will satisfy in the most complete manner possible the needs of all interested, whether in the science or in the art of electrochemistry. Unhampered by precedent in its specific field, it will be conducted along the most advanced lines of modern technical journalism, while at the same time adhering to the [illegible] traditions which have given such an enviable character to the higher class of the American technical press.

Owing to the considerable space allotted to [illegible] chemical industries of Niagara in view of the [illegible] there of the American Electrochemical Society, [illegible] is somewhat circumscribed in the scope of [illegible]. Among the distinctive features represented, [illegible] call attention to the value of the review of the electrochemical periodical literature of the world, the analysis of current electrochemical patents, the first section of a digest of United States patents relating to electrochemistry which hereafter will appear in larger installments, and the first of a series of articles treating from the standpoint of practice the chemical and electrical principles upon which electrochemical applications are based. We are happy to announce that [illegible] leading electrochemical authorities of the world are represented to become regular editorial collaborators and each issue will contain an article from the pen of one of these. With the sincere desire that our columns may be worthy of the great industry they represent, we earnestly solicit [illegible] readers where they may further the value of the journal to art and the science; and we beg their indulgence where they may find us lacking, for any shortcoming will not be from want of devotion to the cause in which these pages are [illegible]

## THE NIAGARA MEETING OF THE AMERICAN ELECTROCHEMICAL SOCIETY.

The second general meeting of the American Electrochemical Society will be held at Niagara Falls from September 15th to 18th. While the Society is now only five months old, it has passed its infancy and has met with a success far beyond the fondest hopes of its most enthusiastic promoters. The inaugural meeting at Philadelphia will long be remembered by all who attended it; there was an unbounded enthusiasm displayed by all then present, there was a great variety of good papers, and for the first time in the United States electrochemical engineers and electrochemists came in close contact with each other. But however great the success of the Philadelphia meeting, the gathering at Niagara bids fair to be even more successful. The beauties of the Falls are ever fresh, and to the electrochemist Niagara reveals still other charms; for the first time several of the large plants of this principal center of the electrochemical industries of the world will open the doors of their workshops to the public. The programme shows again a large variety of papers on important and interesting subjects, and the presence of German and British electrochemists gives an international flavor to the whole affair. We think that the meeting will turn out a success stimulating alike to the young society and to the interests which it so splendidly represents.

## HYDRO-ELECTRIC POWER AND THE ELECTROCHEMICAL INDUSTRIES.

Perhaps the fullest statistical data on the electrochemical industries thus far published are given in a paper read by Dr. W. Borchers before the German Electrochemical Society in 1899. The capacity of all electrochemical plants of all the world at that time is given at 421,220 horse-power, of which 378,350 horse-power, or 90 per cent., is obtained from water-power. Though somewhat stale with reference to such a swiftly advancing industry, these figures nevertheless serve to emphasize a fact brought out in Dr. Richards' valuable article and in the interesting communication by Mr. W. McA. Johnson, published in this issue, namely, that the electrochemical industries have been enabled to make such remarkably rapid progress in recent years through the availability of cheap electric energy generating from water-power. The development of industrial Niagara Falls is an object lesson in this respect.

The development of large water-powers for electrical purposes was first undertaken with a view to the transmission of the energy over considerable distances, and to reduce the line loss, which increases with the square of the current, the use of relatively low currents was involved or, in other words, the employment of high voltages. Thus for a time hydro-electric power development was associated with high voltages and low current. Somewhat unexpectedly, however, and particularly at Niagara, electrochemical industries began to develop in the immediate vicinity of water power generating plants, and then diametrically opposite requirement demanded fulfillment, namely, low voltages and large currents. The heat generated in a furnace increases with the square of the current, and in electrolytic work the output in a given time is directly proportional to the current used. Therefore, for both furnace and electrolytic work, it is obviously necessary to use as large a current as possible. But the lower the voltage the less the power, which has given rise to the saying that in electrochemistry it is the volts that cost money and the ampères which bring money. While thus electrical engineering in long-distance transmission is essentially high-tension work, it is large-current work in electrochemistry. Special and peculiar engineering problems had to be solved in order to meet the requirements of electrochemical work, and in this connection we direct attention to the admirable article on transformers for electrochemical work, which we publish in this issue, from the pen of Mr. John S. Peck, the transformer designer of the Westinghouse Co.

The inherent engineering difficulties having been successfully overcome, it is but natural that the development of hydro-electric power stations should be rapid. There is every promise of even a greater rate in the future, and the development of electrochemical industries will unquestionably proceed at the same pace; for generating stations are anxious to obtain a uniform, continuous load, and to this end they cannot have better customers than electrochemical industries. Another consideration which will aid and accelerate the progress of industrial electrochemistry in this country is the abundance of valuable ores and minerals in the United States, and the relatively high value of the products to be obtained from the same. Dr. Borchers' statistics bear out this point very well. While the power available in electrochemical plants in this country in 1899 was 86,350 horse-power, or 20 per cent. of the total 421,220 horse-power of all the electrochemical plants of the world, yet the value of the products which can be produced by the 86,350 horse-power developed here per year is $97,500,000, and the corresponding value of the products which can be produced in all the electrochemical plants of the world together is $146,500,000; in other words, in these data the presumptive value of the output of the United States is 67 per cent. of that of the whole world. Richly endowed by nature, there can be no doubt that the United States will be the country par excellence of electrochemical industries. People have long enjoyed our beautiful mountains and waterfalls for aesthetic reasons. The electrochemist takes a deeper view; he thinks of the ores in the mountains and of the power in the waterfalls. He feels that here lies dormant the strength and the future of the electrochemical industry. In this sense the view of the Falls of Niagara on the front cover of the first issue of the first American electrochemical journal may be considered as symbolic.

## THEORY OF CONCENTRATION CELLS.

The paper on a "Novel Concentration Cell," read by Prof. H. S. Carhart at the Philadelphia meeting of the American Electrochemical Society, was bound to arouse general interest and animated discussion for two reasons: first, certain facts ascertained with his nickel cell apparently overthrow a theory of concentration cells which has been regarded as being well established, and which has, indeed, been looked upon as one of the most prominent achievements of the modern theory of solutions; second, Prof. Carhart not only attempts to refute an old theory, but gives at the same time the foundations of a new one. We are glad to publish in this issue some further results, obtained more recently by Prof. Carhart, and we may await with interest his paper to be read at the coming Niagara Falls

meeting of the American Electrochemical Society. Meanwhile, it may be of interest to give a concise review of the development of the theory of galvanic cells in general and concentration cells in particular, and to point out that which is new in Carhart's theory and to show its relation to older theories.

When, more than fifty years ago, Helmholtz published his famous paper on the conservation of energy, he made a brief attempt to give a theory of the galvanic cell, under the assumption that the total chemical energy disappearing during electrochemical action is changed into electrical energy; this gives at once a simple relation between the e. m. f. of a cell and the formation heat of the chemical processes in it. Wm. Thomson (now Lord Kelvin) studied this matter shortly afterward, in greater detail, and since then it has become the custom to call that simple relation Thomson's rule. It was found, however, later that the fundamental supposition upon which this rule is based, is not quite correct. In electrochemical actions we have not simply a change of electric energy into chemical energy and *vice versa*, but heat also takes part in the process. By applying the two principles of thermodynamics to the problem, it was found that a correction factor, due to the heat effect, had to be added to the Thomson rule; the modified rule is now generally called the Gibbs-Helmholtz equation.

In the meantime the attention of some investigators had been directed to the study of a special and very simple type of cell, namely, what we now call a concentration cell, *i. e.*, a cell in which the total change of chemical or internal energy corresponds to a change of concentrations. Helmholtz was again the first who in 1877 attacked this problem on the basis of the principles of thermodynamics. He devised an ingenious reversible isothermic cycle in which the concentration cell is first discharged and then the concentration changes are made retrograde by means of isothermic distillation; by applying the principles of thermodynamics to the cycle, he found a relation by which the e. m. f. of a concentration cell can be calculated if the aqueous vapor pressure over the electrolyte is known as a function of the concentration of the electrolyte. A bold step forward was then made by Nernst in 1889. At first glance Nernst's theory appears to be something entirely new, but a more careful analysis soon reveals the fact that he uses the two principles of thermodynamics just in the same way as Helmholtz did, but while he does so, he also makes use of the very distinct assumptions of the electrolytic dissociation theory concerning the constitution of an aqueous solution, and also of some additional ingenious assumptions concerning the so-called solution tension at a reversible electrode. The results which Nernst obtained in this way are in general accord with Helmholtz's theory—naturally because they are based upon the same broad principles—but as Nernst uses suppositions of his own, his results go further; he obtains a very distinct mechanical illustration or model of what happens in a concentration cell, and he can then apply his results to galvanic cells in general. He localizes the sources of e. m. f. at the electrodes and the junctions of different concentrations or different electrolytes, and he resolves the whole electrochemical action in a galvanic cell into a mechanism of ions. His theory of concentration cells has been confirmed repeatedly by measurements, until Prof. Carhart described his nickel cell, which seems to contradict Nernst's theory.

To understand and appreciate the recent work of Prof. Carhart, it is necessary to refer to an important paper published by him in 1900 in the *Physical Review*. Prof. Carhart starts from the correct idea that the Gibbs-Helmholtz equation represents our most assured and best-established knowledge of the relation between the electric, thermic and chemical quantities in an electrochemical system; he starts from this equation and makes an important step to elaborate it. Heat is either taken in or given out by the system, or both occur at the same time at different points of the system. This is the object of Prof. Carhart's investigations. He localizes the heat effect at the two electrodes and separates them; thus instead of one temperature coefficient of the e. m. f. in the Gibbs Helmholtz equation, he gets a sum of two, referring to the two electrodes. This is evidently a step in the right direction; he accomplishes the result that at least part of the total action is localized; while Nernst obtains the same result to a far greater degree by theoretical speculations, Carhart does it by experiment. Prof. Carhart's modification of the Gibbs-Helmholtz equation is valid for any galvanic cell; but it can evidently be best tested by a concentration cell with very dilute solutions; for the change of internal chemical energy, corresponding to concentration changes in very dilute solutions, is practically zero, hence in such a concentration cell we have practically an exchange only of electrical and heat energies. This consideration has evidently led Prof. Carhart to take up the study of concentration cells. He has built up his nickel cell exactly as concentration cells are generally built up; he has two nickel electrodes in two solutions of nickel sulphate of different concentrations. This does not prove, however, that this is really a concentration cell in the sense of Nernst's theory. Nernst in developing his formula, assumes that in a concentration cell of this type, the metal goes into solution at the anode and is deposited upon the cathode. In the experiments published by Carhart there is nothing to prove that this really takes place in his nickel cell; indeed, we have good reasons to doubt it in view of the established fact that during discharge the current in the nickel cell flows from the concentrated to the dilute solution. For we would be led to the conclusion that during discharge the dilute solution becomes more dilute and the concentrated solution becomes more concentrated, and this would be in contradiction with the second principle of thermodynamics, which is used by Prof. Carhart himself for establishing his theory. Hence it is quite probable that the chemical action at the electrodes in the nickel cell is somewhat different; it may be that chemical energy is here changed into other forms of energy; then we would not be justified to call it a concentration cell, and there would be no contradiction with Nernst's theory. While the sensational disagreement with Nernst's theory would then disappear, the general important value of Carhart's work, as sketched above, would not be diminished. There is no doubt that by Prof. Carhart's general formula we will be enabled to get a deeper knowledge of what happens in a galvanic cell, without making any doubtful hypothesis, but simply by experimental work. The very interesting results obtained by Prof. Carhart with the Daniell cell are alone sufficient to prove the value of his theory.

## THE AMERICAN ELECTROCHEMICAL SOCIETY.

The American Electrochemical Society will hold its second general meeting at Niagara Falls, September 15, 16, 17, 18, 1902. The meetings will be devoted to the reading of papers, and the afternoons and evenings to visits and social meetings.

Members and guests will register and receive their badges as soon after their arrival as possible. Badges will be given to all members in good standing and to applicants who have deposited their formation fee. Special badges will be provided for guests, who must be introduced by a member.

*Monday morning, September 15th, at 9 A. M.*

Meeting of Board of Directors at International Hotel.

*Monday morning, September 15th, at 10 A. M., in the music room of the International Hotel.*

Reading and discussion of the following papers:

Francis A. J. Fitzgerald, Niagara Falls, N. Y.: "Note on Testing Carbon Electrodes."

Prof. J. W. Richards, Ph.D., Lehigh University, Bethlehem, Pa.: "Efficiency of Electric Furnace Operations."

P. G. Salom, Philadelphia, Pa.: "Additional Notes on Lead Reduction."

Alfred T. Weightman, Niagara Falls, N. Y.: "Cathodic Reduction."

Prof. Louis Kahlenberg, Ph.D., University of Wisconsin, Madison, Wis.: "Differences of Potential between Metallic Cadmium and Solutions of Cadmium Iodide in Various Solvents."

*Monday afternoon, September 15th, at 2.30 P. M.*

Inspection of power house of Niagara Falls Power Co. and visits to electrochemical works, to be arranged by the Local Committee, starting from the International Hotel.

*Monday evening, September 15th, at 7 P. M.*

Reception in the parlors of the International Hotel. A Ladies' Committee will co-operate.

8 P. M. Banquet for members and ladies, followed by a ball at the International Hotel.

*Tuesday morning, September 16th, at 9.30 A. M., in the Auditorium of Natural Food Co's Building.*

Reading and discussion of the following papers:

Prof. R. S. Hutton, Owens College, Manchester, Eng.: "The Fusion of Quartz in the Electric Furnace."

Marcus Ruthenberg, Philadelphia, Pa.: "Developments in Electrometallurgy of Iron and Steel."

Prof. H. T. Barnes, Ph.D., McGill University, Montreal, Can.: "Theory and Practice of Continuous Flow Calorimetry."

Carl Hering, Philadelphia, Pa.: "An Apparent Electrochemical Paradox."

C. J. Reed, Philadelphia, Pa.: "Some Phenomena of Electrolytic Conduction."

Prof. Henry S. Carhart, LL.D., University of Michigan, Ann Arbor, Mich.: "The Nickel Concentration Cell."

Prof. W. F. Goldsborough, Lafayette, Ind.: "Electrochemistry at the World's Fair, St. Louis."

*Tuesday afternoon, September 16th, at 2.30 P. M.*

Visits to works and places of interest, to be arranged by the Local Committees, starting from the International Hotel.

*Tuesday evening, September 16th.*

Special search light trip on the Niagara Gorge Railway.

*Wednesday morning, September 17th, at 9.30 A. M., in the music room of the International Hotel.*

Reading and discussion of the following papers:

Axel Reuterdahl, Providence, R. I.: "The Electronic Hypothesis and Its Applications."

Prof. John Langley, Ph.D., Cleveland, Ohio.: "Electrochemical Polarization."

Hugh Rodman, Philadelphia, Pa.: "Storage Battery Invention."

Woolsey McA. Johnson, New Brighton, S. I., N. Y.: "The Electrolytic Dissolution of Soluble Metallic Anodes."

C. W. Volney, Ph.D., Keyport, N. J.: "On the Electrolysis of Sodium Nitrate and the Composition of the Developed Gases."

*Wednesday afternoon, September 17th, at 2.30 P. M.*

Excursion and picnic to Dufferin Islands in Queen Victoria Park. The house and grounds of the Niagara Falls Country Club will be open to members for golf, tennis, etc., and may be reached by trolley from the hotel.

*Thursday morning, September 18th, at 9.30 A. M.*

Reading and discussion of the following papers:

D. H. Browne, Cleveland, Ohio: "Pumps and other Accessories in Electrolytic Plants."

Prof. G. B. Frankforter, University of Minnesota, Minneapolis, Minn.: Subject to be announced.

Titus Ulke, Sault Ste. Marie, Ont., Can.: Subject to be announced.

Several other papers are expected.

*Thursday afternoon, September 18th.*

Private visits to electrochemical plants by personal invitations.

After the above programme had been issued, the following three additional papers were announced:

Alfred H. Cowles, Cleveland, Ohio: "A Unit of Quantity of Electricity for Use in Electrochemical Calculations."

Edw. R. Taylor, Penn Yan, N. Y.: "Some Further Advances on the Closed and Continuous-working Electric Furnace."

Prof. F. Haber, Ph. D., Karlsruhe, Germany: Subject to be announced.

Visits will be arranged to a number of the installations of special interest to electrochemists, as also to places of general interest. Badges will be necessary to entitle members and guests to the privilege of taking part in the visits and excursions.

## PROPOSED BRITISH SOCIETY OF ELECTROCHEMISTS.

For some time past it has been thought to be advisable to form an electrochemical society in Great Britain.

An informal meeting to discuss the subject was held on March 4, 1902, at which a committee consisting of the following gentlemen was chosen to consider the subject: J. Swinburne (the present president of the British Institution of Electrical Engineers), Dr. F. M. Perkin, Dr. Donnan, W. R. Cooper, S. Cowper-Coles and H. V. Simpson. This committee has held meetings from time to time at which the best methods of procedure have been carefully discussed. The question of working in conjunction with one of the existing societies has also been considered, and several societies have been approached on the matter, but the committee takes the view that such an arrangement is not likely, at any rate, for the present, to have the desired effect. They have come to the conclusion, therefore, that the society should be independent. Steps in the direction of organizing this society have just been taken.

It has been suggested that there be two classes of members: full members and associate members, the subscription fee being two guineas and one guinea respectively. (*i. e.*, about $10 and $5).

The honorable secretary of the committee is H. V. Simpson, Grosvenor Mansion, Victoria street, S. W., London, Eng.

We hope the society will be founded and will meet with great success.

## TRANSFORMERS FOR ELECTROCHEMICAL WORK.

By J. S. Peck.

IN electrochemical work the demand is ordinarily for a transformer capable of delivering extremely heavy secondary currents at widely varying voltages, and which shall have a construction sufficiently rugged to stand excessive overloads for short periods and to operate twenty-four hours per day without deterioration.

The transformer which has been almost universally adopted for this work is that known as the oil-insulated water-cooled type. The transformer proper is mounted in a case of boiler iron, which is filled with oil, with primary and secondary leads carried through the top of the case.

The function of the oil is to increase the insulation strength and to carry the heat from the active parts of the transformer, where it is generated, to the cooling surfaces.

Water is almost always used for cooling, but there are a number of different methods of utilizing it. Where the secondary conductors are very heavy they are sometimes made hollow and the cooling water circulated directly through the conductors. This method, while very effective in cooling the secondary winding, takes up valuable space within the transformer, gives a bulky conductor in which eddy currents may be set up and is difficult to make water tight.

Another method consists in pumping the oil from the transformer case to an elevated cooling tank, where it comes in contact with water coils, is cooled and then allowed to circulate by gravity through the transformer.

The system in most common use, however, consists in placing the water-cooling coils within the transformer case below the surface of the oil. This brings the cooling coils into intimate contact with the oil, making a most efficient method of cooling, and one requiring the minimum amount of cooling apparatus and attention.

The design of a transformer for extremely heavy currents involves a number of interesting problems, a full appreciation of which requires a considerable knowledge of electrical engineering.

When a current of electricity flows through a circuit, a magnetic field is set up; if the current is alternating, then the field alternates also and induces a voltage in the circuit opposed or counter to the impressed voltage. The effect of this counter voltage is to cause an increased drop of pressure in the circuit, so that the voltage delivered to the load may be very much less than would be obtained with direct current where the only drop is that due to ohmic resistance.

The amount of this counter voltage increases directly with the current in the circuit and with the frequency or rate of alternations. It also increases as the distance between conductors is increased, and varies somewhat with the size and shape of the conductors themselves.

In electrochemical work, where the volume of current is large and the voltage low, the conditions are favorable for the production of a high percentage of counter voltage, and unless special precautions are taken it may be, with full-load current, almost as large as the impressed voltage, leaving practically no pressure for forcing current through the load.

To reduce this counter voltage the secondary is divided into a large number of parallel circuits, placed side by side, and as near together as mechanical considerations will permit. Thus the current in any one circuit is kept down to a reasonable volume, the conductors are kept close together with a correspondingly reduced counter voltage.

Where a number of circuits are thus operated in parallel it is customary to have each circuit supplied from a separate coil in the transformer, and great care is necessary in the design of the transformer to obtain a symmetrical relation between primary and secondary windings, in order that the voltage induced in all the coils may be the same. If the voltage on the different coils is not the same, then the coil or coils having the higher voltage will force a local current through the coil or coils of lower voltage, which will result in unequal and excessive heating in the coils.

Another element of danger in the design of apparatus for heavy currents is the stray field induced by the current in the conductors. For if this field cuts the large conductors, heavy local or eddy currents may be set up. This trouble is particularly apt to occur inside the transformer, and careful consideration must be given to it when a transformer is designed.

Since the counter voltage induced in a circuit depends upon the rate of alternations, it is obviously desirable to have as low a frequency as possible. For most of the electrochemical work done up to the present time a frequency of 3,000 alternations per minute (or, in other words, 25 full periods per second) has been used, as low a value as is considered feasible for general power distribution. In certain cases, however, where extremely heavy currents at low voltage have been demanded, difficulty has been experienced in keeping down the counter voltage to anything like a reasonable value, and it is probable that for certain electrochemical work a frequency considerably lower than this will be adopted.

In electrochemical work the great majority of transformers are supplied from primary mains, the voltage of which cannot be varied, and as one of the requirements for this work is that the transformer shall deliver a variable secondary voltage, it is necessary that some means of varying the voltage be provided in connection with the transformer itself.

There are two general methods of accomplishing this variation:

1st. By changing the ratio between the primary and secondary turns.

2d. By placing in the primary or secondary circuit of the transformer an auxiliary transformer, having a variable voltage ratio, the voltage of which may be added to or subtracted from that of the main transformer.

Of the two methods the first is ordinarily the simpler and cheaper, and will be first considered.

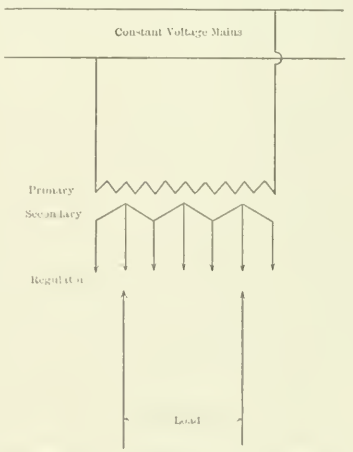

FIG. 1.—REGULATOR IN SECONDARY OF TRANSFORMER.

Fig. 1 shows diagrammatically the primary and secondary windings of a transformer. From the secondary winding a number of taps are brought out, so that by connecting to different taps a varying number of secondary turns may be obtained. If the transformer is supplied from 2,000-volt mains and there are 200 turns in the primary winding, then there will be upon every turn in the transformer 10 volts. If the secondary has 10 turns, the total voltage induced in this winding will be 100. If one of the secondary terminals be moved so

that there are but 5 turns between the two terminals, then but 50 volts will be delivered. If 8 turns are included, then 80 volts will be delivered, etc.

With large transformers there are a number of objections to this method of varying the number of secondary turns. One is that the current in the secondary is so large that it is difficult to change from tap to tap without cutting off the current from the transformer. Another is that the voltage steps obtained are usually too large a percentage of the total voltage to be permissible.

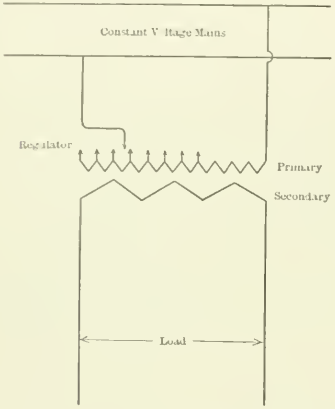

FIG. 2.—REGULATOR IN PRIMARY OF TRANSFORMER.

To avoid this difficulty a modification of this method, shown in Fig. 2, is used. Here the taps are brought out from the high tension winding and means are provided for stepping one line terminal from tap to tap.

If, as before, the primary voltage is 2,000, the primary turns 200 and the secondary turns 10, then with the whole primary winding in there will be 10 volts per turn and 100 volts on the secondary. If half the primary winding be cut out, so that there remains but 100 turns, then there will be 20 volts per turn and 200 volts on the secondary. If the primary voltage is impressed on 150 turns, there will be 13⅓ volts per turn and 133 volts on the secondary winding.

As the primary winding has many more turns than the secondary, it is possible to obtain much smaller steps than when the change in turns is made on the secondary. The primary current is small compared with the secondary, and may be usually handled without serious difficulty.

For changing the line terminal from one tap to another, a regulating dial is required. If the output of the transformer is small, so that the primary current is low and the voltage between taps not excessive, then a dial similar to that shown in Fig. 3 may be satisfactorily used. If, however, the current is very heavy or the volts between steps excessive, it is necessary to supply a more substantial type of regulator. Fig. 4 shows a switchboard type of regulator designed for handling heavy currents, with several hundred volts between steps.

The connections for this regulator are shown in Fig. 5. When switch No. 1 is closed, the line terminals are connected directly across the total winding. If it is desired to cut out turns to raise the secondary voltage, the method of procedure is as follows: switch No. 2 is closed, switch No. 1 is opened, switch No. 3 is closed and switch No. 2 is opened. When switches No. 1 and No. 2 are closed at the same time, a resistance "R" prevents a short circuit and excessive flow of current between the points 1 and 2 on the transformer winding. The same condition exists when switches No. 2 and No. 3 are closed at the same time. When switch No. 3 is connected to the line and all others open, it is evident that the line terminal X is connected directly to the transformer winding at 3, thus cutting out entirely turns between 1 and 3.

On this particular regulator the switches were operated by hand one at a time. It is, however, desirable to have the different switches actuated by a common shaft driven by a crank at the end of the board, and such an arrangement may be easily adapted to a regulator of this type. The great merit in this form of regulator is that the construction is exceedingly simple and substantial, so that there is little danger of the

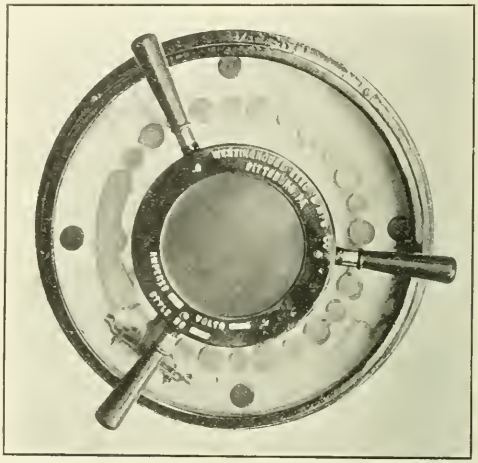

FIG. 3.—REGULATING DIAL.

troubles developing in this regulator which are common to many regulators of the dial type.

The second system of regulation, which consists in placing a regulating transformer in series with the primary or secondary of a transformer, may be operated in a number of different ways.

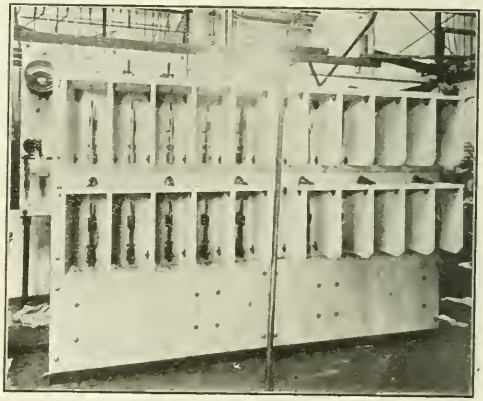

FIG. 4.—SWITCHBOARD TYPE OF REGULATOR.

Fig. 6 shows a regulating transformer placed in the secondary of the main transformer. To vary the voltage of the regulating transformer the number of turns in the secondary are changed as indicated in the diagram. When the voltage of the regulating transformer is in such a direction as to assist that of the main transformer, the voltage applied to the load will be the sum of the secondary voltage of main and regu-

lating transformer. When the voltage of the regulating transformer opposes that of the main transformer, the voltage on the load will be equal to the difference between the voltage of the main and that of the regulating transformer.

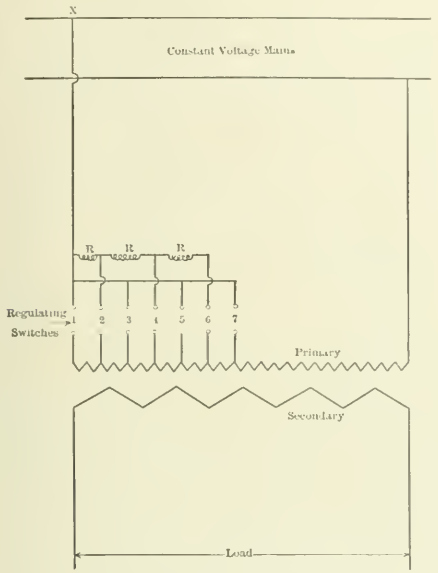

FIG. 5.—CONNECTIONS OF REGULATOR.

The objection to this particular method lies in the difficulty of handling, on any type of regulator, the heavy currents in the secondary circuit; also to the fact that the voltage steps obtainable are ordinarily larger than is permissible.

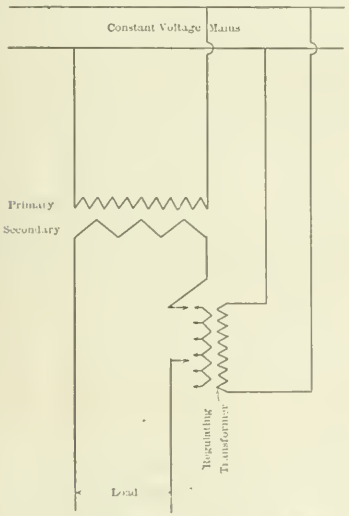

FIG. 6.—REGULATING TRANSFORMER IN THE SECONDARY OF THE MAIN TRANSFORMER.

Fig. 7 shows the same type of regulating transformer, but connected in the primary circuit. When so placed the currents to be handled are much smaller and finer adjustments in voltage may be obtained.

Fig. 8 shows a method of regulation in which the ratio of primary and secondary turns in the regulating transformer is maintained constant, the voltage being varied by changing the voltage impressed upon the primary of the regulating trans-

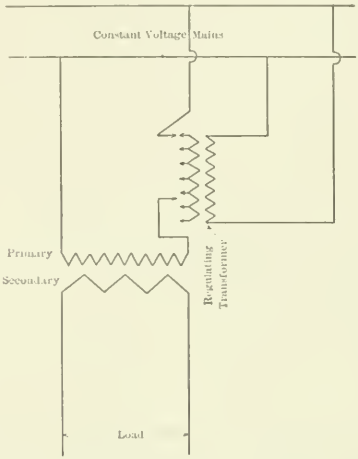

FIG. 7.—REGULATING TRANSFORMER IN THE PRIMARY OF THE MAIN TRANSFORMER.

former. The variable voltage for the regulating transformer is obtained from an auxiliary "auto" or single-coil transformer. With this scheme the current in the regulating circuit may be kept down as low as desired by choosing a suitable voltage for the primary of the regulating transformer. Fig. 8 shows the regulating transformer in the secondary circuit, but it could obviously be as well placed in the primary circuit.

Fig. 9 shows a modification of the method shown in Fig. 8. Here the primary of the regulating transformer is supplied

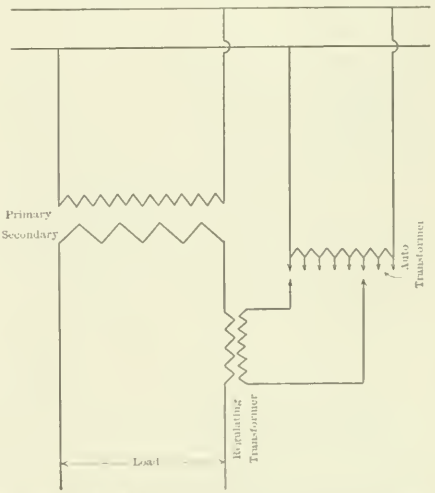

FIG. 8.—METHOD OF REGULATION BY MEANS OF A REGULATING TRANSFORMER AND AN AUXILIARY AUTO TRANSFORMER.

from taps which are brought out from the primary winding of the main transformer, thus doing away with the necessity of the auxiliary auto transformer.

In all the methods of regulation which have been described

the variation in voltage is obtained by the step-by-step method, although the main circuit of the transformer is never opened, so that current is never cut off from the load. In certain classes of electrochemical work it is necessary that the voltage be varied gradually, moving by steps. Where this is required, it is customary to place in series with the primary or secondary winding of the main transformer the secondary of an induction regulator (see Fig. 10). This regulator is a form of trans-

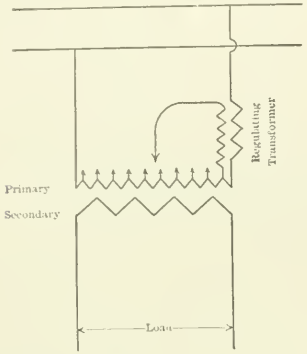

Fig. 9.—Modification of the arrangement of Fig. 8.

former so arranged that the primary and secondary windings may be moved inductively with relation to each other, so that by a proper movement the secondary voltage of the regulator can be varied from 0 to a positive or negative maximum, the change in voltage being at a perfectly uniform rate. The objection to this form of regulator is its high cost and low efficiency as compared with regulators of the step-by-step type.

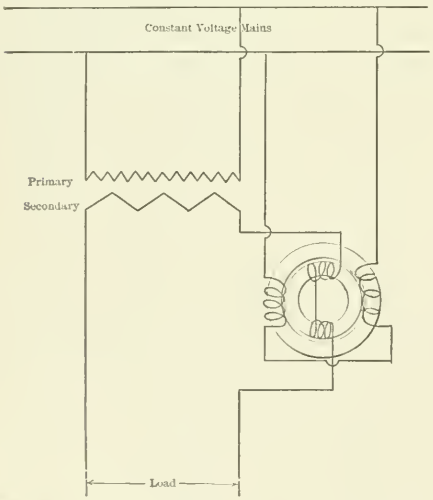

Fig. 10.—Method of regulating the voltage at a uniform rate.

To say that the construction of transformers and regulators for delivering heavy currents at variable voltages has kept pace with the growth of the electrochemical industry is sufficient to indicate the development along this line. But such is the case, and the limit to the amount of current or range in voltage will not be set by the transformer designer, but rather by commercial considerations and the demand of the electrochemical industry.

## IONIC VELOCITIES IN LIQUID AMMONIA SOLUTIONS.*

By Prof. Edward C. Franklin and Hamilton P. Cady.

Measurements of the electrical conductivity of salts dissolved in liquid ammonia have shown that such solutions carry the current with remarkable facility, surpassing in this respect even aqueous solutions themselves. As an example may be cited the case of potassium nitrate, which in solution in liquid ammonia shows the following conductivity as compared with aqueous solutions at the same concentrations:

| Dilution | Molecular Conductivity of $KNO_3$ in $NH_3$ at $-33°$ | $H_2O$ at 18° |
|---|---|---|
| 1 | ..... | 75.2 |
| 10 | 88.0 | 103.7 |
| 100 | 138.5 | 114.0 |
| 1,000 | 245.0 | 119.0 |
| 10,000 | 319.0 | 122.0 |
| 50,000 | 337.0 | 121.5 |
| 70,000 | 338.0 | ..... |

Other salts show an entirely similar behavior.

The rapid increase in the molecular conductivity with dilution and its final high value are interpreted as meaning that in the more concentrated solutions the salts are dissociated to a much smaller degree in ammonia than in water, and that to complete the dissociation in ammonia solutions the dilution must be carried much higher than is necessary in the case of aqueous solutions. Referring to the table given above, it will be seen that while dissociation is well on towards completion in water solutions at a dilution of 1,000, in ammonia solutions, on the other hand, the dilution must be carried up to somewhere between 10,000 and 50,000 in order to bring about the same degree of dissociation.

Now, if liquid ammonia solutions are to meet the requirements of the theory of electrolytic dissociation, it is necessary to assume that the ions in this solvent travel at a much greater speed than they do in aqueous solutions. It was to determine by direct measurement the velocity with which a number of anions and cations travel in liquid ammonia that the present investigation was undertaken.

The method used consisted, for example, in the case in which the velocity of a cation was to be measured, in noting the speed with which the boundary between two solutions containing a common anion traveled up a graduated tube. The solution containing the cation whose speed was to be measured was superimposed upon a solution containing a heavier and slower cation. The velocity with which the meniscus moves up the tube is conditioned only upon the faster cation, the slower, heavier cation serving merely as an indicator. The details of the somewhat complicated piece of apparatus, together with the complete data, will be published in the near future.

The results obtained are as follows, compared with the speeds of the same ions in water solutions:

| | Velocity in cm per sec per volt. in $NH_3$ at $-33°$ | in $H_2O$ at 18° |
|---|---|---|
| Ammonium | 0.00133 | 0.00055 |
| Potassium | 0.00167 | 0.00057 |
| Sodium | 0.00132 | 0.00035 |
| Silver | 0.00103 | 0.00046 |
| Nitrate ion | 0.00166 | 0.00053 |
| Bromine ion | 0.00168 | 0.00059 |

These values are in very fair agreement with the conductivity measurements of Franklin and Kraus.

* Abstract of a paper read at the Pittsburg meeting of the A. A. A. S., July, 1902.

## CONTRIBUTIONS TO THE THEORY OF CONCENTRATION CELLS.*

By Prof. Henry S. Carhart.

The two classes of simple concentration cells are:

1st. Two electrodes of the same metal immersed in a solution of a salt of this metal, the density of the solution at the two electrodes being different.

2d. Two electrodes consisting of an amalgam of the same metal, the concentration of the metal in the amalgam being different at the two electrodes, both immersed in a solution of a salt of this metal.

The usual Nernst formula for the electromotive force of a concentration cell requires that the direction of the electromotive force through the cell shall be from the dilute to the concentrated solution. Considerations derived from the thermo electromotive force at the contact of metals and their salts, led the author to construct a concentration cell of the first of the above classes in which the direction of the electromotive force within the cell is from the concentrated to the dilute solution. It consists of nickel immersed in a solution of nickel sulphate or chloride.

In the Nernst formula the electromotive force is proportional to the absolute temperature. This suggests a thermal origin for the electromotive force of a concentration cell. From this point of view *concentration cells are devices for converting the heat of their surroundings into electrical energy.*

The same conclusion is reached when one considers the Helmholtz equation for the electromotive force of a voltaic cell. It may be written

$$E = \frac{H}{q} + T\frac{dE}{dT}.$$

H is the heat equivalent of the chemical reactions. If the temperature coefficient is positive, the energy given out by the cell is greater than the chemical energy transformed, or the element tends to cool and to take heat from its surroundings. In general, as the author has shown in another paper, heat is absorbed on one side of the cell and is generated on the other side. In the Daniell cell the two almost exactly counterbalance each other.

If the Helmholtz equation is generally applicable, then where there are no chemical reactions to furnish energy, the only source of electrical energy is heat. The electromotive force is then obviously thermal. From this point of view the nickel concentration cell does not constitute an exception, save that the thermo-electromotive force is directed from the metal to the solution of its salt, while with zinc, copper, silver, cadmium, etc., it is the other way.

These facts are not sufficient to explain the electromotive force of a concentration cell without the aid of another law, which the author has discovered, namely, the law of the increase of the thermo-electromotive force with the concentration of the solution, and of its decrease with the increase of the concentration of the metallic ion in the amalgam. Hence, the thermo-electromotive forces on the two sides of the cell do not balance each other, and the residual explains the electromotive force of the concentration cell. Curves were shown exhibiting the relation between thermo-electromotive forces and concentrations, both as regards solutions and amalgams. Hence, both classes of simple concentration cells are explained by means of the thermo-electromotive forces at the contact between the electrodes and the solution.

Since the thermo-electromotive force increases with the concentration of the solution and decreases with the concentration of the ion in the amalgam, it should be possible to offset the one with the other. A single trial with zinc amalgam and zinc-sulphate solutions gave a cell with an electromotive force of only 0.0004 volt.

The law of the increase of the thermo-electromotive force with the concentration of the solution explains two well-known facts about the Daniell cell:

1st. Its electromotive force increases with the density of the copper sulphate solution and decreases with the increase in density of the zinc-sulphate solution. With these metals the thermo-electromotive force is directed from the solution to the metal. It is, therefore, clear that any increase in the concentration of the copper-sulphate solution must increase the thermal component of the electromotive force of the cell, and conversely with the zinc-sulphate solution. The only other explanation of this fact ever given is based on osmotic pressure.

2d. It is known that the temperature coefficient of the Daniell cell at ordinary concentrations is negative; that with concentrated copper sulphate, and zinc sulphate solution having a density of about 1.04, it becomes zero; with a still weaker zinc sulphate solution, the temperature coefficient is positive. This fact is readily explained when one remembers that the temperature coefficient of the cell is the resultant of all the thermo-electromotive forces at the several contacts. The one at the $Zn\text{-}ZnSO_4$ reduces the electromotive of the cell or tends to make the temperature coefficient negative. By reducing the concentration of the zinc sulphate solution this thermo electromotive force is reduced till it is smaller than that at the copper plate, and then the temperature coefficient of the cell becomes positive.

* Abstract of a paper read at the Pittsburg meeting of the A. A. A. S. July, 1902.

## ELECTROCHEMISTRY AS AN ENGINEERING COURSE.

By Prof. C. F. Burgess, E. E.

The establishment of a four years's course in applied electrochemistry finds its justification in the marked development of the electrochemical industries and the consequent demand for men having a special training. The marked differences of opinion which have been expressed as to what electrochemical training should consist in, arises from differences of opinion as to what the product should be, whether an electrochemical engineer or an electrochemist.

The industrial development of electrochemistry has been the result of adapting former and well-known laboratory experiments to large-scale industrial practice more than to new scientific discoveries, and progress along this line will undoubtedly continue. Chemical manufacturing was a number of years ago considered best developed when the processes were so simple that no power was necessary to assist in the chemical reactions, but this condition has changed and the chemical industries are now pre-eminently power-using industries. This has been the result to a large degree upon the use of electrical energy either in the electrolytic cell or the electric furnace for producing chemical changes.

A knowledge of the properties of materials of construction and of the transformations, distributions and utilization of various forms of energy is, therefore, essential for an electrochemical engineer, and such knowledge can best be obtained in an engineering course, conducted along much the same lines that are followed in electrical, mechanical, or other engineering courses.

Something over a year ago the Engineering College of the University of Wisconsin established a four years' course with the object of furnishing such training, and designed in accordance with the idea that the electrochemical engineer should be primarily an engineer, with however a considerable knowledge of chemistry and chemical engineering subjects. The principal difficulty is that a great amount of laboratory work is necessary in connection with most of the required studies, and the amount of time which should be devoted to all of them is hard to crowd into a four years' course.

* Abstract of a paper presented at the recent Pittsburg meeting of the Society for the Promotion of Engineering Education.

## PIONEERS OF ELECTROCHEMISTRY—I.

### Charles M. Hall.

CHARLES M. HALL, inventor of the Hall process for producing aluminum, was born at Thompson, Geauga County, Ohio, on December 6, 1863. His father is a Congregational minister, and moving to Oberlin in 1873, young Hall attended the public schools there and later Oberlin College. At college he took the classical course, graduating in 1885. During the course he had one term of chemical study with Professor Jewett, and was so captivated with the subject that for nearly a year thereafter he experimented in the Oberlin laboratory, with the special object of finding an electrical method of commercially producing aluminum. The detailed history of these attempts is as follows:

Hall's experiments were made with a galvanic battery as the source of his current, and a gasoline burner to heat his crucibles. His idea was that alumina was the cheapest aluminum compound, and that if he could find some easily-fusible salt which would, when molten, dissolve alumina, he might, by electrolysis, obtain from the bath aluminum and oxygen, just as copper and chlorine are obtained by electrolyzing an aqueous solution of copper chloride. His early experiments failed because of using clay crucibles, and it was not until he lined the crucibles with a mixture of ground gas-retort carbon and tar that he succeeded in producing the metal. This was on February 23, 1886. The solvent bath then used was cryolite, the double fluoride of aluminum and sodium.

Charles M. Hall

In the summer of 1886 he went to Boston, where his brother, a clergyman, raised money to continue the experiments, power was rented and four months' work done with a small dynamo. The basic patent for the process, using for the solvent bath a double fluoride salt of aluminum and of a more electropositive metal, was applied for on July 9, 1886. Much of the work at Boston was directed towards working the bath with copper anodes, which, indeed, work to some extent, by becoming oxidized superficially, but have since been proven decidedly inferior to carbon anodes. The finding of the best anodes to use in the bath consumed practically two years' time, and, meanwhile, the work at Boston was discontinued, after four months of effort.

Returning to Oberlin, in the fall of 1886, Hall stuck with dogged perseverance to his task of developing a commercial process. He constructed a large bichromate-sulphuric acid battery of 12 cells, each a gallon capacity, casting the zincs himself by melting down scrap zinc. He had no current-measuring instruments, but, working with small iron crucibles, 2 inches in diameter, carbon lined, obtained lumps of metal one-quarter ounce in weight, at a run. The work was carried on mostly with the use of potassium fluoride in the bath, instead of sodium fluoride. This bath is more easily fusible than the sodium bath, but is not so permanent, and, therefore, not so suitable for a continuous process. The results, however, were encouraging, and in December, 1886, Hall went to Cleveland, where an uncle resided, in order to raise funds to work on a larger scale.

Negotiations with Cleveland capitalists lasted some six months, the principal stumbling block being the division of interests in the future commercial development of the process. Hall was willing to give a good share of his patent rights for funds to continue developing his process, but insisted on having at least one-fourth interest in the company organized to work the process. Meanwhile, the United States patent office declared an interference between Hall's application and that of Héroult, and this forced matters to a head, so that in the summer of 1887 Hall entered into an agreement with the Cowles Electric Smelting and Aluminum Co., under which Hall was to have electric current and facilities for experimenting at the Cowles works, at Lockport, N. Y., giving in return a six months' option on his process, in exchange for a certain fraction of the stock of that company. After six months the option was renewed for three months more, but at the end of nine months the option ceased, without the company carrying it into effect. Mr. Cowles' statement of their reason for letting the process pass from their control is that the results, as far as they saw, were not sufficiently encouraging. Mr. Hall's statement is that he figured up that he then made aluminum at the rate of one pound per horse-power per twenty-four hours, but that the current at his command was so small that he would work many hours over a hot fire to make a few ounces of aluminum, and that all that was needed was to apply the process on a larger scale. We will go no further into this controversy, which probably never will be settled satisfactorily to all concerned, and so we merely state the two sides.

Romaine Cole, also employed at the Cowles works, undertook at this juncture to interest capital in the process. He interested Capt. A. E. Hunt and Mr. Mellon, the banker, of Pittsburg, and in August, 1888, the Pittsburg Reduction Co. were organized, with a capital of $20,000, and work on an installation being at once commenced, the company were turning out aluminum commercially by November, 1888.

Meanwhile, the interference in the patent office had been decided in favor of Mr. Hall, and the business was clear of incumbrance and entered on an era of continuous development.

In 1891 the plant was moved to New Kensington, 16 miles from Pittsburg, on the Allegheny River; in 1893 a contract was made with the Niagara Power Co. and the "upper works" started, using 1,800 horse-power, in 1895, and since increased to 3,600 horse-power. In 1896 the "lower" Niagara plant was started, using 3,500 horse-power, since increased to 6,500 horse-power. Since then the company have bought bauxite mines in Georgia and Arkansas, have started a 5,000 horse-power reduction plant at Shawinigan Falls, Quebec, and are commencing on a 10-acre plant at Massena, N. Y., which will utilize 12,000 horse-power.

In connection with these developments, Mr. Hall has invented several important improvements.

# NIAGARA AS AN ELECTROCHEMICAL CENTRE.

## THE ELECTROCHEMICAL INDUSTRIES OF NIAGARA FALLS.

By JOSEPH W. RICHARDS, PH.D.
*President of the American Electrochemical Society.*

THE second meeting of the American Electrochemical Society, inaugurated in Philadelphia, April 3d, of this year, is with the greatest propriety scheduled to be held at Niagara Falls, in September, of this year. Although Philadelphia may with right claim to be the birthplace of the American Electrochemical *Society*, Niagara Falls may with equal right claim to be the home, *par excellence*, of the American electrochemical *industry*. Here, within a radius of two miles from the greatest source of water-power in the world, have grown up within the short space of eight years more than a dozen varied electrochemical industries; here, using power which costs less than half as much as power can be generated from coal (even if the coal were to be had for nothing), have grown up and developed into commercial successes processes which but a decade ago were merely ideas, visions in the fancy of a few electrochemical enthusiasts. The old adage, "knowledge is power," is being improved upon: the keynote of success at Niagara is "knowledge *and* power."

No field in the whole range of the applied sciences is succeeding more signally, promising more attractively, or so pregnant with suggestions of future applications, than electrochemistry. In the hands of the masterful chemist, acquainted with the facts of chemistry and the needs of civilization, the uniting and decomposing powers of the electric current, its almost infinite control of chemical analysis and synthesis, the generation of inconceivable temperatures on a commercial scale and the methods it furnishes of torturing poor Mother Nature into new shapes and wringing from her new secrets, has brought to realization fancies which were undreamed of by the alchemists.

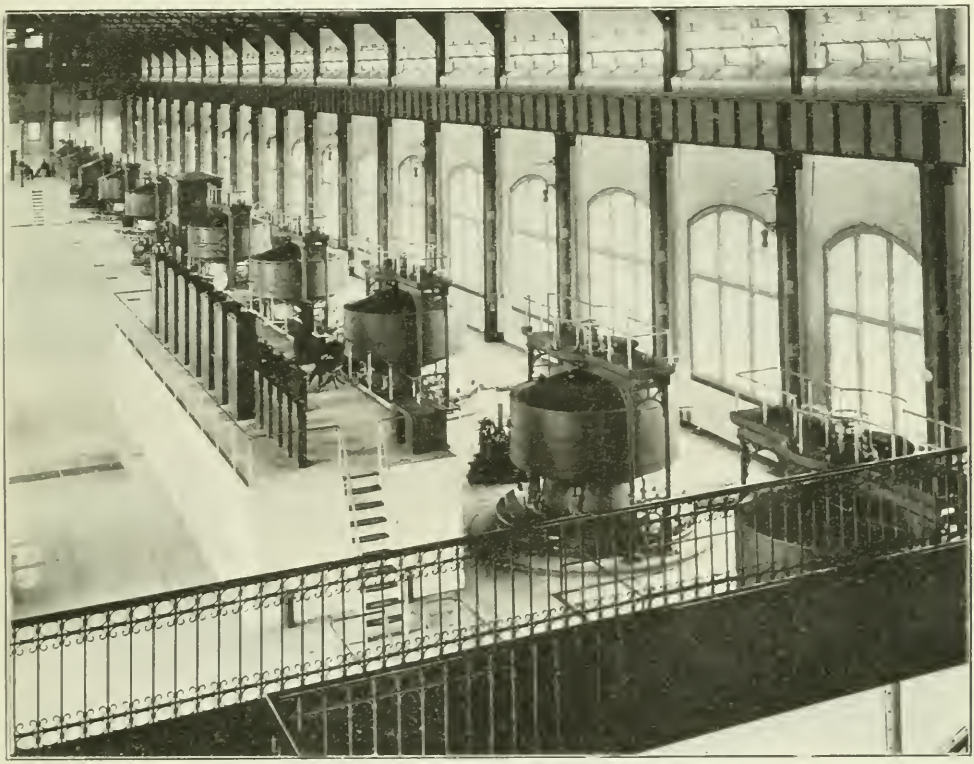

FIG. 1.—POWER HOUSE NO. 1, NIAGARA FALLS POWER CO.

Combined with all the necessary supply of power, Niagara unites almost every other requirement for commercial development. The great lakes, with 3,000 miles of shore line, and navigable to the very docks at Niagara, give the cheapest sort of transportation to markets representing nearly half the population of North America, besides furnishing in many cases the cheapest sources of raw materials. Railways radiate therefrom in all directions; and, to add to it all, the falls with their great facilities are equally within two different countries, under different governments, one on a protection basis as regards imports, the other practically free trade, and the manufacturer can take his choice as to which policy is most favorable to his industry. He can even place one works in America,

NOTE.—Owing to limitation of space, descriptions of the following plants are reserved for the following issue: Pittsburg Reduction Company, International Acheson Graphite Company, Carborundum Company and Acker Process Company.—ED.

to enable American trade to come to Canada, to supply foreign trade. Truly, Niagara does present an almost embarrassing combination of advantages.

The canal to the edge of the gorge was built in 1861, and supplied power to several works and mills, who utilized from 20 to 50 feet of the possible 160-foot fall thus supplied. The canal was purchased by the Niagara Falls Hydraulic Power and Mfg. Co. in 1887, who increased the facilities for providing power and supplied it to some additional shops; but the great consumers of power—the electrochemical industries—were not yet far enough developed to enter the field, and the development of this great water power had to wait upon the opening of the electrochemical industry for its great *raison d'être, the developing electrochemical industry gave incentive for and is practically the mainspring of the development of power at Niagara Falls.* By the end of this year the Niagara Falls Power Co. will be developing 60,000 horse-power, 45,000 of which, or exactly three quarters, will be used in electrochemical work.

The Hydraulic Power and Mfg. Co. have a canal, 36 feet wide and 8 feet deep, reaching from above the falls to the sides of the gorge below the town, on the American side, giving a head of 210 feet to the river below. Their principal power plant is located in the gorge at the water's edge and develops 30,000 horse-power, while 5,000 horse-power additional is generated by several smaller plants using only part of the available head, as is shown in the photograph by the various cataracts descending the cliff. This company have now the right to enlarge their canal to 100 feet in width by 14 feet in depth, which will give, it is estimated, a total of over 100,000 available horse-power. The selling price of this power varies from $8 per horse-power per year, for those buying only the water right and putting in their own machinery, to $20 or $25 per horse-power per year for those buying the working current, adapted to their particular use.

The Niagara Falls Power Co., on the American side, above the falls, have wheel pits, 180 feet deep, connected with a tail-race tunnel, 21 feet in diameter by 1⅓ miles long, whose capacity to take away water is rated at 120,000 horse-power. The

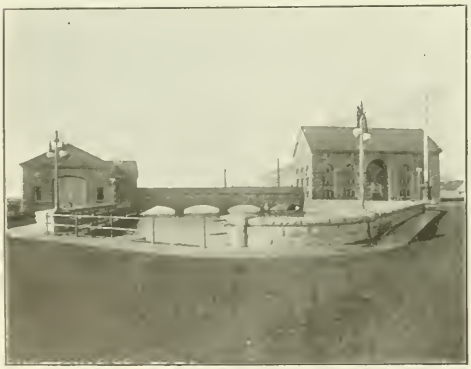

FIG. 2.—POWER HOUSE NO. 1 AND TRANSFORMER STATION, NIAGARA FALLS POWER CO.

per horse-power per year, transforming it at their own cost in present working station has ten 5,000 horse-power units in operation, and 5,000 horse power additional to operate the local street railway system. The International Paper Co., located alongside this power house, have their own wheel pit and generating machinery, and use the tunnel for their tail race, thus employing 10,000 horse-power, for which is paid $9 per year. Other companies using power from this plant receive the current at 2,250 volts, alternating, and pay for it $18 to $20 whatever way may be necessary for their special purposes. This company own 1,500 acres of ground, which is reserved for manufacturing purposes, and held at about $1,000 per acre. The company are at present constructing a 55,000 horse-power plant, which is already under roof (as shown in photograph) and which will furnish the first 10,000 of their power in October, and it is an interesting feature that several of the works are now erecting additions, and that this first 10,000 horse-power was all contracted for several months in advance.

FIG. 3.—STATION NO. 2, NIAGARA FALLS POWER CO.

The Canadian-Niagara Falls Power Co. pay the Canadian Park Commission $25,000 per year for the right to develop 250,000 horse-power on the Canadian side. Their power house, immediately to the left of the falls, is well under way, and will begin furnishing power in July, 1903. Other concessions have been made allowing 200,000 horse-power more to be developed on the Canadian side, but they are not yet being exploited.

### THE CASTNER ELECTROLYTIC ALKALI CO.

This company were originally the Mathiessen Alkali Co., a branch of the Providence works of that company, and operated the Castner process first at Saltville, Va., in 1895. The present company may be considered the American representative of the Castner-Kellner Co. of England. The officers are B. F. Thurston, president; Max Mauran, superintendent. The patents operated under are those of H. Y. Castner (U. S. Patent 528,322, of 1894), and Max Mauran (U. S. Patents 674,927 and 674,930 to 674,934). The patent of Mr. Castner (who is now deceased) is the basic one, covering the principle of using a compound cell with movable mercury floor, partitions dipping into the mercury separating the cell into compartments, which are electrically independent of each other, and moving the mercury from one compartment to another by any mechanical means. The patents of Mauran are directed towards greater mechanical perfection of the details of the cells, but in no wise alter their principle of action.

The Castner cell, as installed by Mr. Castner, at Niagara, is a slate box, 4 feet wide, 4 feet long and 6 inches deep, the joints being made by rubber cement. Two partitions reaching within 1-16 of an inch of the bottom (under which are made grooves) divide the cell into three compartments, each 15 inches wide by 4 feet long, which are made independent of each other by mercury on the bottom and in the grooves, touching the partitions. The general plan of the process and its theory are so well known that it is unnecessary to rehearse them here, and we will confine our description to the actual apparatus used. The exterior compartments, through which brine flows, have numerous graphitized carbon anodes passing

FIG. 4. STATION OF THE NIAGARA FALLS HYDRAULIC POWER AND MFG. CO.

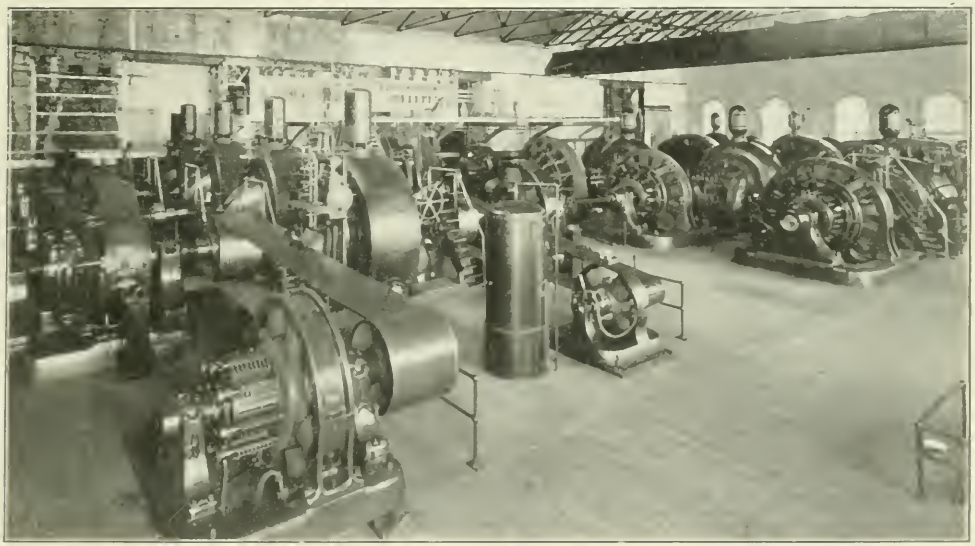

FIG. 5. NIAGARA FALLS HYDRAULIC POWER AND MFG. CO'S STATION IN GORGE.

through the sides of the box with 1 inch of the surface of the mercury. There are 12 electrodes on each side, each 1 inch in diameter by 15 inches long. These compartments are provided with tight covers and exit pipes of rubber, connecting with lead pipes to carry off the chlorine. The central compartment has 20 sheets of iron hanging in it, which serve as cathodes for liberating hydrogen in the caustic soda solution. This compartment is supplied with pure water; it is covered loosely with a sheet lead cover, and the liberated hydrogen escapes into the room. The cell is pivoted on two points on one side and rests on an eccentric on the other, which raises and lowers about ¼ inch, once a minute. This suffices for the circulation of the mercury between the outer, or charging, and the inner, or discharging, compartments. The current passes through the brine in the outer compartments, liberating chlorine at the graphite anodes and charging the mercury with sodium; it then passes from the mercury in the central compartment to the iron cathodes, liberating hydrogen therein and setting free caustic soda in the solution. Only 90 per cent. of the charging current is allowed to pass through the discharging cell, because the efficiency of charging is not quite 100 per cent., while that of discharge is 100 per cent. or over, and the margin of 10 per cent. must be allowed in order not to oxidize the mercury by having a deficiency of sodium to discharge. This appears to be one of the severest difficulties of the process. The salt solution flows through continuously; the salt is from

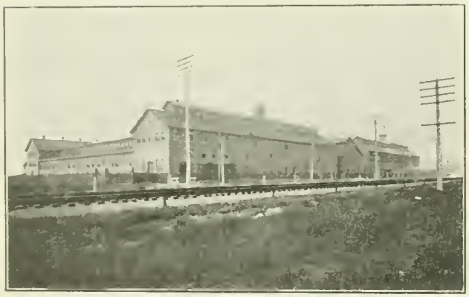

FIG. 6.—CASTNER ELECTROLYTIC ALKALI CO.

the New York beds at Retsof, containing very little magnesium and but a small proportion of sulphates. The strong salt solution is not purified before going to the cells. On returning, it is strongly charged with chlorine, and has to be pumped by earthenware pumps. The sulphates accumulate to a certain point, when part of the solution is withdrawn from circulation, purified by use of barium chloride and returned to the circulating system. Water is run into the center compartments and allowed to remain until it has reached a certain concentration (54° Twaddell), and then run off and replaced by fresh water. The caustic solution is evaporated to solid caustic in iron pans, 10 feet in diameter by 6 feet deep, and it will be readily seen that the stronger the solution from the cells the less evaporation is needed. The cells last indefinitely, the graphite anodes last one to two years, the iron cathodes are unchanged. The mercury is unattacked as long as sufficient of the charging current (averaging 10 per cent.) is shunted off from passing through the discharging cell. If the operator is anxious to "sail close to the wind" he may shunt off too little, and immediately blacken the mercury and cause the formation of mercury salts. Each cell contains in the neighborhood of 100 pounds of mercury, which costs more than the rest of the apparatus. (Slate apparatus is made in the Pennsylvania slate regions at prices hardly greater than if made of wood.)

The improvements on the original Castner cell by Mr. Maurau have been as follows: a more efficient cathode has been made, the iron sheets being replaced by an iron grid (like an inlet grating), consisting of 20 strips the length of the cell, 1 inch deep and about ½ inch apart, united at the ends, where they rest on the cell walls, in order to make connections. The graphite rods passing through the sides of the box gave frequent trouble from leakage and offered considerable resistance. They have been replaced by blocks having much the shape of a rail section, which are cemented into the lid of the compartment, with their broad lower flanges offering large surface within ½ inch of the mercury, their upper parts projecting above the lid are connected by zigzag lead connections and paraffined heavily to preserve the contacts. The voltage necessary to run the cells has thus been decreased some 20 per cent.

Each cell receives 630 ampères and absorbs 4.3 volts. The voltage absolutely necessary for the decompositions is 2.3 volts, so that 53 per cent. of the energy of the current is actually used in the chemical transformation and 47 per cent. converted into heat. The watts thus converted into heat are, however, only 1,260, which would suffice to keep the cell only a few degrees above the normal temperature. The temperature of the cell may, in very hot weather, approach the danger line of 40° C., at which chlorate begins to be produced, but artificial cooling has not yet been found necessary with the current densities used. The current density at the mercury is 110 ampères per square foot, at the graphite anodes probably 150. The efficiency attained, calculating on the ampères of the charging current, is very close to 90 per cent.

The first plant at Niagara Falls, situated three-quarters of a mile above the upper power house, occupies a tract of ground 150 yards square. It contains storage rooms, power-converting plant, cell room, 200 feet square, evaporating house with ten evaporating pots and large bleaching-powder chambers. The power room contains ten stationary converters, each connected with a rotary converter. The 2,250-volt alternating current, supplying 700 ampères, is thus split up into currents of 70 ampères each, which are converted by the ten rotaries into ten currents of nearly 200 horse-power each, *i. e.*, 230 volts by 630 ampères. Each such current runs a double row of 54 cells in series. The theoretical quantity of materials treated per day of twenty-four hours, reckoning on an efficiency of 90 per cent., is as follows (in pounds):

| | Per Cell | Per 540 Cells | Per H.-P. |
|---|---|---|---|
| Crude salt decomposed..... | 65.25 | 35,200 | 17.6 |
| Caustic soda produced..... | 44.62 | 24,100 | 12.0 |
| Bleaching powder produced (36 per cent. chlorine).... | 111.54 | 60,200 | 30.1 |

The plant at Niagara was enlarged in 1901 by the construction on a neighboring site of a 4,000 horse-power plant, working on the same principles. The whole plant at Niagara represents, therefore, a capacity of 6,000 horse-power, using over 50 tons of salt daily, and producing therefrom 36 tons of caustic soda and 90 tons of bleaching powder. The 3,000 horse-power Acker process plant has about the same capacity as the 2,000 horse-power Castner plant. Between the Acker and Castner processes it is estimated that they produce nearly one-half of the caustic soda made in America.

Analyses of the caustic soda produced by the Castner process show it to contain 97 to 99 per cent. caustic, 1 to 2 per cent. of sodium carbonate (from contact with the air), 0.3 to 0.8 per cent. of sodium chloride, 0.03 to 0.10 per cent. of sodium sulphate and 0.05 to 0.10 per cent. of sodium silicate. The sulphate comes mostly from the water used to take up the caustic, the chloride from leakage from the brine chambers and the silicate from corrosion of the slate cells.

### THE NIAGARA ELECTROCHEMICAL CO.

This company were formed to work the processes of H. Y. Castner for producing sodium, sodium peroxide and sodium cyanide. The manufacture of the first two is conducted at

Niagara, of the latter at Roessler and Hasslacher's works at Perth Amboy, N. J. The company were incorporated in 1895, and the principal stockholders are the Aluminum Co., Ltd., Oldbury, England, the Deutsche Gold and Silber Scheide Anstalt vormals Rossler, of Frankfort, Germany, and Rossler and Hasslacher, 100 William street, New York. The English and German firms named also conduct similar manufactures under Castner's patents. The officers of the company are Franz Rossler, president; J. Hasslacher, secretary and general

FIG. 7.—NIAGARA ELECTROCHEMICAL CO.

manager, and Geo. F. Brindley, chemist and manager of the Niagara plant. The capital is $100,000.

Castner's patent for producing metallic sodium is the U. S. Patent 452,030, of May 12, 1891; for producing sodium peroxide, U. S. Patent 494,757, of April 4, 1893; for producing cyanides, U. S. Patents 541,006, of June 18, 1895, 543,043, of July 30, 1895, and 577,837, of March 2, 1897. Only the first named is an electrochemical process.

The process consists, according to its claims, in electrolyzing caustic alkali constantly maintained at not more than 20 degrees above its melting point; and, also, in using a gauze or screen between the electrodes and a superposed dome for collecting the metal. The temperature must be kept low in order to prevent the resolution of metal by the bath and re combination, which take place actively at higher temperatures. Caustic soda melts at 308° C., if pure, but down to 300° if it contains slight impurities. It is electrolyzed preferably within 10° of its melting point, but never above 325°. Within five degrees of its melting point, almost the theoretical quantity of sodium is obtained, at ten degrees above, about 90 per cent., and this is the best attainable in commercial practice, above this the yield decreases very rapidly, and at 50 degrees above its melting point re combination is so active as decomposition and the bath yields no metal. At this "dead

On commencing to pass the current through melted caustic soda, any water present is at first decomposed, evolving hydrogen and oxygen only until every trace of water has gone. After that sodium and hydrogen together appear at the cathode, and oxygen at the anode. These must be kept rigorously separated or re-oxidation of the sodium will ensue, and the hydrogen will be oxidized, with an explosion. Castner achieves this by hanging a gauze or screen all around the cathode, the meshes of which are large enough to allow the electrolyte to circulate through it freely, but small enough to prevent either globules of sodium or bubbles of hydrogen or oxygen gas from passing through. The sodium collects on top of the electrolyte, and is thence run off or ladled out.

Castner's apparatus consists of a conical iron pot, 18 inches in diameter by 2 feet deep, set in brick work. The carbon cathode comes up through the bottom, through a fireclay tubular prolongation, 12 inches long, in which to build caustic sets and forms a tight joint. The top of the rod has a enlargement 4 inches in diameter, standing about 3 inches and

side of the pot; this is the active cathode. Surrounding this is a 6-inch circular anode of iron or, better, nickel, and between these is a 5-inch circular cylinder of nickel mesh, suspended from a solid 5-inch cylinder, which reaches above the surface of the caustic and is covered over by an iron lid having small holes for escaping hydrogen. Such a pot holds 250 pounds of melted caustic, and a current of 1,200 amperes is passed through it, dropping 5 volts in a pot. The current density at the cathodes is, therefore, about 2,500 amperes per square foot and at the anodes 1,500. Four rows of 10 such pots are in operation at this plant, using 1,000 horse-power and producing daily, at an assumed efficiency of 90 per cent., 52 pounds of sodium per pot, or 0,250 pounds for the whole plant. This is a little less than 4 horse-power per hour per pound of sodium, whose cost would be only 2 cents. Since caustic soda costs only 2 cents per pound or 4 cents per pound of sodium produced, and the labor should not amount to over 3 cents per pound, while deterioration of apparatus remelting and packing may be put at 2½ cents more, the minimum cost of sodium by this process is probably not over 10 cents per pound. Its market price is 35 cents per pound, but the demand for the metal is limited. The greater part of the product is converted into sodium peroxide, by passing air over the sodium at a certain temperature in iron tubes. The product contains 95 to 97 per cent. of peroxide and 3 to 5 per cent. of carbonate and moisture, and commands 35 cents per pound in ton lots.

The *bete noire* of the sodium business has always been the limited demand and restricted uses for the metal. That this company is successfully solving the problem is evidenced by the doubling of the size of the works last year. The present plant covers two acres and employs 60 men. May they see increase!

### THE NORTON EMERY WHEEL CO.

This is an old-established firm, located at Worcester, Mass., which have purchased from the Ampere Electrochemical Co. the patent of Chas. B. Jacobs for fusing bauxite in an electric furnace and thereby producing a pure artificial corundum. This process consists in fusing the natural bauxite and allowing it to cool slowly, when it acquires the hardness of

FIG. 8.—[illegible]

corundum and the machines are nearly [illegible] wheels, emery paper and cloth, [illegible] abrasives.

The process was originally patented at the time of the Ampere Electrochemical Co., by a reduction furnace of the Harvey Jarbuh type. During the process [illegible] electrodes carbon [illegible] [illegible] [illegible] and bauxite is [illegible] [illegible] and [illegible] [illegible] [illegible]

The works of the Norton Emery Wheel Co. are situated about one mile above the upper power house, and is a brick building, two stories in height, covering 60 by 90 feet, erected in 1901. The gentlemen in charge are A. C. Higgins, general manager, and S. F. Hall, superintendent. The building contains office, laboratory, calcining furnace and melting furnaces. The bauxite is first taken to the upper floor, where it is charged into the upper end of a calcining furnace fired by coal. Here the bauxite is completely calcined, and is taken out at the lower floor level. It is then hoisted to the upper floor, where the melting furnaces are operated. The power used is 500 horse-power. The method of operation is similar to that of the experimental work already described, and is carried on in furnaces into which dip the two carbon terminals. These terminals dip into the melted bath, and fresh bauxite is added as soon as the contents are melted. The method of regulating the distance of the carbons in the bath and of protecting the furnace lining are matters which have been very satisfactorily solved.

After a run the carbons are taken out and the mass allowed to cool three or four hours in the furnace, after which the block is removed from the furnace and left on the floor to cool. Then it is broken up into pieces of convenient size, roughly sorted and shipped to the main works at Worcester, Mass. The best product is horny, or flinty in appearance, while some beautiful small crystals of pure alumina are at times found, colored blue, like sapphire, or pink, like ruby. They are, in fact, the artificial gems, but too small to possess value as such.

### THE UNITED BARIUM CO.

This company were formed to acquire and work the processes of working barium sulphate into other barium salts, which was developed to commercial working by the Ampère

Fig. 9.—United Barium Co.

Electrochemical Co. The officers of the company are G. S. Ettla, president; W. H. Miller, vice-president; J. G. Petrekin, treasurer, and T. L. Welles, works superintendent.

The process acquired is that patented by C. S. Bradley and C. B. Jacobs (U. S. Patent 624,041, of 1899; German Patent 111,667, of December 16, 1898). The principle employed is that of melting in an electric furnace a mixture of barium sulphate with a small quantity of carbon, usually only one-nineteenth of its weight. If sufficient carbon is present, all the sulphate is reduced in the electric furnace to sulphide, according to the reaction

$$BaSO_4 + 4C = BaS + 4CO$$

requiring one part of carbon to five parts of sulphate, and reproducing the ordinary furnace reaction for making the sulphide. If barium sulphate and barium sulphide are fused together, at the heat of an electric furnace, however, they will react according to the formula

$$3BaSO_4 + BaS = 4BaO + 4SO_2,$$

but this reaction cannot be produced at ordinary furnace heats. If, therefore, just one-fourth as much carbon is used as is necessary to reduce the sulphate to sulphide, the one-fourth of sulphate reduced to sulphide reacts upon the unchanged three-fourths and the oxide is obtained. The sum total of the two reactions, written altogether, is

$$BaSO_4 + C = BaO + SO_2 + CO.$$

The reaction is not perfect, however, and in general only about two-thirds of the sulphate is converted into oxide, nearly one-third remains as sulphide and only a very small fraction remains unchanged, some 1 to 3 per cent.

There are two furnaces now in operation working this process. They are of the direct-heating arc type, the carbons being adjustable and playing an arc onto the fused material. The body of the furnace is lined with carbon blocks, and the contents are tapped out from time to time as the furnace gets full of melted material. The carbons are raised and lowered by means of small electric motors, controlled by the workmen, and pass through a square opening in a grid of wrought-iron pipes, cooled by a stream of water, and covered with a non-conducting cover. The workmen can thus feed in material while standing close to the furnace, but the mixture of barium sulphate and carbon must be fed in slowly, because the gases evolved by the reaction are large in volume and would cause violent boiling if melted too quickly. Attempts are being made to recover the sulphur dioxide evolved, so as to convert it into sulphuric acid. Each ton of sulphate furnaced gives off enough of this gas to make one-half a ton of 50 per cent. sulphuric acid.

The plant is being enlarged so as to manufacture 60 tons of barium hydrate, $Ba(OH)_2 \cdot 8H_2O$, per day. The present output is stated to be 12 tons daily. There are three 400 horse-power furnaces, each taking 2,500 ampères at 120 volts, and at this output, allowing that only 60 per cent. of the sulphate is reduced to oxide, the efficiency of the furnaces would count up 74 per cent. absorbed in heating up and melting the mixture and in the chemical reactions, while 26 per cent. would be lost by radiation.

The furnace product is tapped out, running into cakes about 3 feet by 4 feet and 3 inches thick. This is broken up and digested with hot water, leaving very little insoluble sulphate, but the material is about 60 per cent. barium oxide and 40 per cent. barium sulphide, which go into solution as 60 parts hydrated oxide, 20 parts sulphide and 20 parts sulphydrate. On cooling the filtrate, the hydrate, $Ba(OH)_2 \cdot 8H_2O$ crystallizes out and is separated in centrifugals. When dried and packed it sells at 3 cents per pound. The mother liquors are treated to recover their barium as carbonate and also to recover the sulphur in them, by methods which are not yet quite worked out and which the company are not ready to publish.

The raw material, barite from Missouri, costs $2.50 per ton where found, but the railway freight raises its cost to some $6 per ton at Niagara. It is about 90 per cent. pure. To obtain cheaper material, the company have acquired a remarkable deposit of barite on the north shore of Lake Superior near Silver Island. The cliff here is 50 feet high, and a vein of pure white barite, 77 feet wide, with perpendicular strike, is exposed for the whole height of the cliff and is visible 30 feet down in the water, while it has been traced on shore a distance of 600 feet back from the water. At a moderate calculation, 250,000 tons of barite are in sight, which can be shipped from the spot to the company's wharf at Niagara more cheaply than Lake Superior iron ore can be carried to Pittsburg.

The uses of the company's products are various. Barium hydrate finds application in the paint trade, for making white paints; in the sugar trade, for recovering sugar (as insoluble

barium saccharate) from waste dilute solutions, and for softening boiler waters. The mother liquors from the crystallization of hydrate, containing barium sulphide and sulphydrate, have been found useful in removing hair from hides, a solution diluted to 2½ per cent. removing all the hair from a hide in 3½ hours' immersion, without any injury to the leather. The same solution is very suitable for making the white paint called *"lithophone,"* which is made by running a solution of zinc sulphate into barium sulphide solution, thus producing the precipitated pigment, a mixture of barium sulphate and zinc sulphide. The mother liquors can also be converted into barium carbonate, which has found application in the cyanide industry and also in the manufacture of bricks; for mixed in small proportion with the clay it is said to prevent red bricks from turning white and white bricks from turning green.

Such are some of the many ramifications of the electrical-barium process, and in the further prosecution of that most interesting business we wish our Niagara friends *bon voyage.*

THE OLDBURY CHEMICAL CO.

This company are virtually the American branch of Albright and Wilson, manufacturing chemists of Oldbury, England. Their New York agents are J. L. and D. S. Riker, Cedar street, New York. Hugh A. Irvine is the manager. The plant is near that of the Roberts Chemical Co., and uses 1,000 horse-power in the production of yellow phosphorus and potassium chlorate. The works cover 3½ acres and employ 60 men. The output of chlorate is given as 30,000 pounds per month and that of phosphorus an equal amount. If these figures are reliable, the current efficiency of the works is exceedingly high, compared with others in the same lines.

The Readman-Parker process of producing phosphorus is used, in which natural phosphate is intimately mixed with carbon and sand, and placed in a retort-like furnace heated inside by the electric current passing between carbon poles, it being a type of resistance furnace. The phosphorus distills off and is condensed under water, the calcium silicate slag is tapped out intermittently. About 80 to 90 per cent. of the phosphorus in the raw material is recovered and only 170 pounds a day are obtained from one furnace. *(Mineral Industry,* Vol. VII.) It would take, therefore, six furnaces to make the output quoted, which would be of 50 horse-power each.

Mr. Irvine has patented an improvement on the method of heating the charge in his furnaces (U. S. Patent 681,367) consisting essentially in using a granular core of carbon as a heating agent, surrounding it with the charge material and passing the current. As soon as the charge melts, forming a body of slag, the carbon floats up and the current thenceforth passes through the slag, which then serves as the vehicle for melting fresh portions of charge.

THE AMPÈRE ELECTROCHEMICAL CO.

This company are a decided innovation, in that they are not an operating company, but an experimenting company, formed to discover and develop new electrochemical processes and bring them to the point of commercial application. The founders of this company were Prof. F. B. Crocker, president; C. A. Doremus, vice president; S. S. Wheeler, treasurer; C. S. Bradley, inventor, and they have associated with them A. H. Buch, H. E. Knight, D. R. Lovejoy, Chas. B. Jacobs and N. Thurlow as chemists. The company originally located at Ampère, N. J., but in 1898 established themselves at Niagara. The processes so far developed by this company are as follows: the method of fusing bauxite to produce artificial corundum, sold to and now operated by the Norton Emery Wheel Co.; the method of treating barite (natural barium sulphate) to produce barium hydrate, sold to and now operated by the United Barium Co.;

FIG. 9.—OLDBURY CHEMICAL CO.

the method of producing nitric acid from nitrogen and oxygen, operated by the Atmospheric Products Co.; a method of producing camphor from turpentine, discovered by Mr. Thurlow, and being now installed at Port Chester, N. Y., on a scale sufficient to produce one ton of camphor per day. Besides these, the company are working on the production of cyanides by the fixation of atmospheric nitrogen, the production of artificial rubber, the production of new fertilizers and the manufacture of several new silicides. We will consider by themselves the processes already being operated at Niagara by other companies, and will under this heading describe only those processes of the Ampère Electrochemical Co. which are in process of development.

*Manufacture of Cyanides.* By heating a mixture of barium oxide or carbonate with carbon in the electric furnace, barium carbide quite similar to calcium carbide is obtained. Its formula is $BaC_2$, and it is very probable that it is an unsaturated compound of the same type as acetylene, $H_2C_2$, and, therefore, containing two carbon atoms, which temporarily neutralize each other's affinities. Such compounds easily form additional compounds, and it has been found that by heating the barium carbide and passing nitrogen gas over it, the latter joins onto the carbon and forms barium cyanide, $BaC_2N_2$. Air will not

[illegible] oxygen would oxi[illegible] but the oxygen must either [illegible] which may be done [illegible] a process amounting to [illegible] With this gas as the reagent, the cyanide [illegible] but little oxidation. The mass being [illegible] the cyanide goes into solution, and may [illegible] soda salt, such as the carbonate, to [illegible] and leave in solution the sodium [illegible] Another alternative is to treat the barium cyanide [illegible] with dilute acetic acid, under reduced [illegible] and passing the hydrocyanic acid gas into caustic soda [illegible] produce the cyanide, leaving barium acetate behind. The [illegible] evaporation and distillation of the latter in a closed [illegible] leaves behind barium carbonate and distills off very pure [illegible] much purer than is commercially obtained from cal[illegible] acetate. The barium carbonate is then used over.

The company are now working industriously on the commercial installment of the process above outlined, which, experimentally, has promised very good results.

*Manufacture of Ammonia.*—There is a possibility that by passing steam over the barium cyanide, ammonia may be made in commercial quantities by the reaction

$$BaC_2N_2 + 3H_2O = BaO + 2NH_3 + 2CO.$$

The writer does not know how far this possibility has proven successful

*Manufacture of Silicides.*—In July, 1899, this company succeeded in producing the silicides $CaSi_2$, $BaSi_2$ and $SrSi_2$, which are analogous to the carbides $CaC_2$, etc. (U. S. Patents to Jacobs, 656,353 and 656,354, of 1900). They are formed in the electric furnace by heating to a comparatively high temperature (higher than that needed for carbides) a mixture of carbonate, oxide, sulphate or phosphate of the metal concerned with silica and sufficient carbon to effect the reduction; as, for instance, according to the reactions

$$BaO + 2SiO_2 + 5C = BaSi_2 + 5CO.$$
$$BaSi_2O_5 + 5C = BaSi_2 + 5CO.$$

These silicides are crystalline, bluish-white, and in contact with water give pure hydrogen, by the reaction

$$BaSi_2 + 6H_2O = Ba(OH)_2 + 2SiO_2 + 5H_2.$$

One pound of calcium silicide will thus generate, in a common acetylene generator, 18.5 cubic feet of pure hydrogen; or it would require 54 pounds per 1,000 cubic feet of hydrogen. These qualities suggest a field for generating hydrogen in the laboratory or for ballooning purposes. It is also stated that barium silicide has the property, if put into melted iron or steel, of combining with the sulphur and phosphorus present therein, removing them in the slag as barium sulphide or phosphide, and experiments made on steel at Newark are said to have succeeded in removing the injurious sulphur and phosphorus completely. They are also good reducing agents, working in either acid or neutral solutions.

*Manufacture of Camphor and Rubber.*—These are made from turpentine by a purely chemical process, not electric, so their consideration is here omitted.

These are but a part of the ideas which this company are working up into commercial processes, and if one considers the combination of forces which this company command—some veteran inventors, some college professors, some college-trained chemists and electricians, some business men, and all enthusiastic, persevering workers—it is safe to predict that many more valuable processes will be brought to light as their record

THE ELECTRICAL LEAD REDUCTION CO.

This company were organized to work the electrolytic method of reducing lead sulphide or native galena, patented by Pedro G. Salom, of Philadelphia. The officers are Pedro G. Salom, president; Henry G. Morris, vice president; F. H. Deacon, secretary and treasurer. The chemist is A. L. Weightman; superintendent, S. Weil. The company have a paid-in capital of $200,000, they issue preferred stock $2,000,000 and common stock $10,000,000.

The process has been described by Mr. Salom in the *Transactions of the American Electrochemical Society*, Vol. I, 1902. The idea of the process is, briefly, to use crushed and pure galena as cathode in a dilute solution of sulphuric acid, where it is reduced, the sulphur going off as hydrogen sulphide. Two Westinghouse 300 horse-power motors are run on the

FIG. 11.—ELECTRICAL LEAD REDUCTION CO.

alternating current of 2,250 volts, and each is directly connected with a Westinghouse direct-current 250 horse-power generator. The reduction pans are of antimonial lead, 15 inches across at the bottom and 18 inches at the top, round and 6 inches deep. The galena is spread on the bottom in a layer of fine material, 1 inch thick, dilute sulphuric acid is put in, the sides of the pan are protected by a rubber lining, and the bottom of a similar pan placed on top becomes the anode. The pans are thus stacked 11 high, the bottom of each pan serving as anode to the pan beneath it. Thirty-three pounds

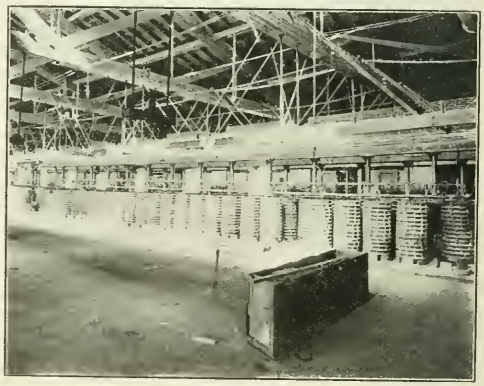

FIG. 12.—CELL ROOM, ELECTRICAL LEAD REDUCTION CO.

of galena is thus subjected to a current of .33 ampères, requiring 2.9 volts, and is treated 5 days. The ore is reduced *in situ* to spongy metallic lead, swelling up to 3 or 4 inches thickness. The gases escaping are a mixture of hydrogen and hydrogen sulphide, the proportion of the latter in the gas gradually increasing from zero to a maximum, in one day, and then gradually declining. The stacks are grouped in fours, run in parallel, so that the current of 125 volts runs through four stacks in series (equals 44 pans) and runs through several of such groups in parallel.

The cell room is 140 by 182 feet, and has room for 10 rows of 22 stacks each, whose capacity would be 10 tons of lead per day. Only two of these rows have been installed so far, but the rest of the room is being filled with an improved type of cell, which works much more quickly and satisfactory, and which will be described by Mr Salom before the Niagara meeting of the American Electrochemical Society, on September 15th, next. This apparatus is particularly designed to obviate the incompleteness of reduction, which has given considerable trouble

The gases escaping are conducted in lead pipes to a combustion chamber, where they are burned, either completely, so as to recover sulphuric acid, or incompletely, so as to recover sulphur. The spongy lead is first washed on a sloping table, with a hose, and using a hoe in order to remove light impurities, such as quartz, zinc sulphide, etc. It is then dried in a revolving cylinder of iron over a furnace. It is then ready for use in storage batteries. Most of it is converted into litharge, by burning it carefully on the hearth of a reverberating furnace. In this way an hour's treatment converts it completely into litharge, which is cooled, washed, to remove any unconverted lead, and dried. The product is clean and pure, and finds a ready market with glass and rubber makers. Mr. Salom has also patented processes for the conversion of this sponge into other lead salts, such as carbonate, chromate, dioxide and for pressing it into a compact storage-battery plate.

The process is based on sound electrochemical principles and also sound economic principles. The electrochemical equivalent of lead is so high that very little electric power is needed to reduce it; theoretically, for instance, a current which would liberate 1 part of aluminum would set free 11½ parts of lead. The process furnishes the lead in a condition highly suitable for solution or corrosion or conversion into other lead salts, while it is in exactly the condition required for storage-battery work. If Mr. Salom can secure the complete reduction of all galena, his process will have an economic future which his present Niagara plant will not be able to take care of.

### THE ROBERTS CHEMICAL CO.

The plant of this company is nearly two miles from the upper power house. It is a one-story frame building, 60 by 200 feet, and utilizes 500 horse power in the manufacture of caustic potash and hydrochloric acid from potassium chloride. The officials of the company are W. S. Block, president; H. G

FIG. 13.—THE ROBERTS CHEMICAL CO.

Wilson, treasurer; S. D. Benobiel, general manager; Ross Phillips, chemist. The company own and operate the patents of I. L. Roberts (U. S. Patents 673,452 and 673,453) for electrolytic apparatus and connections. No further details of the working of this company are available.

### A. L. ROSSI.

This veteran pioneer in the field of ferro-titanium is still reducing titanium ores on a semi commercial scale at Niagara Falls. His 200 horse-power furnace is situated in a stone building between the plants of the Electrical Lead Reduction Co. and the Acheson Graphite Co. Here he is reducing ilmenite, titanic iron ore containing 65 per cent. of ferric oxide and 35 per cent. of titanic acid, in the electric furnace, producing at will a high ferro-titanium, or, by using iron as flux, an almost pure cast iron. He makes two grades of ferro-titanium, one with 4 per cent. of titanium, for use in cast-iron foundry work, and the other with 10 per cent. titanium, for use in steel. The 4 to 5 per cent. alloy melts easily at the heat of a foundry cupola, or of ordinary coal fuel, and is particularly valuable for making a high quality of car wheel castings. The 10 per cent. alloy melts at the heat of a steel-melting furnace and is claimed by Mr. Rossi to impart wonderful virtues to steel.

### THE NATIONAL ELECTROLYTIC CO.

The plant of this company is below the falls, and they receive direct current of 2,000 horse-power from the power

FIG. 14.—THE NATIONAL ELECTROLYTIC CO.

house about 500 feet away. The plant at Niagara manufactures potassium chlorate under the patents of W. T. Gibbs, viz. U. S. Patent 665,426 and 665,427, of January 8, 1901, for the manufacture of chlorates, and U. S. Patent 665,679, of same date, for an electrolytic apparatus.

The process used consists in principle in the electrolysis of a solution of potassium chloride, using a copper or iron cathode and a platinum anode, the electrodes being but a very small distance apart, using a high current density, a temperature above 40° C. and no porous partition. Under these circumstances, chlorate is abundantly formed, passes out of the apparatus before the solution contains a high percentage of it and is crystallized out by cooling the solution. The efficiency of the operation is a datum which the company do not desire to publish, their first experiments were said to have yielded 55 to 60 per cent. of the theoretical amount of chlorate, and their present practice is somewhere nearer to 70 per cent. efficiency.

The apparatus employed consists of rectangular wooden frames, 18 by 20 inches inside, alternating with lead plates, placed together in a frame like a filter press, with rubber gaskets between. One side of the ¼ inch gaskets is against the iron or lead plate, the other against the copper or iron cathodes. The wooden frames being covered with lead, to furnish electrical connection from cathodes to anodes. The anodes are platinum foil supported on the lead or iron plates. They are unattacked. The cathodes were originally of iron gauze, covered with oxide of copper, it being found that the hydrogen there set free would reduce these oxides and thus depolarize the electrode and diminish the potential necessary for running the cell. Such cathodes were not satisfactory and have been replaced by bare copper. They are in the form of rods, forming a grid with transverse strengtheners, and with insulating rods to keep them from touching the anodes from

a little less than 1-64 of an inch distant. The distance of these 2 inches between the pairs of electrodes allows a considerable volume of solution to present itself for electrolysis, and, being well circulated, obviates the difficulties which would otherwise arise from having the electrodes within 1-64 of an inch of each other. The open, grid-like formation of the electrodes renders this scheme effective. Solution of potassium chloride runs into each cell continuously, at the rate of about one gallon for each thirty minutes, at a temperature of 20° C., and its flow is so regulated that the temperature of the effluent streams above 40° C. and averages 70° C. The chlorate formation takes place properly as the temperature keeps above 40° C., being interfered with greatly by impurities in the solution, such as insoluble or colloidal precipitates.

Any number of such cells may be put into one frame, in form like a filter press, with rubber gaskets between and screwed up water tight. The current is then passed through them in series, with a current of 1,650 ampères, giving a current density at the anode of 500 ampères per square foot. Since the conversion of chloride into chlorate absorbs 1.4 volts in the decomposition, about one-third of the energy of the current is used up in chemical work, while two-thirds are converted into heat, sufficient, theoretically, to raise the temperature of the cell 5° C. per minute, if it were not kept cool by the circulation of the electrolyte. The issuing stream is from 65° to 70° C., and foamy from evolving hydrogen. A cell of this kind is said by Kershaw (article in the *London Electrician*) to have been patented to Gibbs and Franchot in 1893, to have been experimented with in 1895 and to have given, on a two months' trial, 4,386 pounds of chlorate per horse-power per day, which is an efficiency of 67 per cent.

The manufacture of potassium chlorate is one of the oldest of electrochemical manufactures, but an inspection of the plant of this company certainly justifies the statement that their arrangement of plant and manner of working are not excelled, and probably not equaled by any other works in this line of business.

THE ATMOSPHERIC PRODUCTS CO.

This company are an offshoot from the Ampère Electrochemical Co. They were incorporated early in 1902, with a capital stock of $1,000,000. Chas. S. Bradley is president and D. Ross Lovejoy, electrician. The process was evolved by Bradley and Lovejoy, and has been worked out in detail mostly by Mr. Lovejoy. The U. S. Patent is allowed, but not yet issued; the English Patent is 8,230, of June 8, 1901. The patent is for

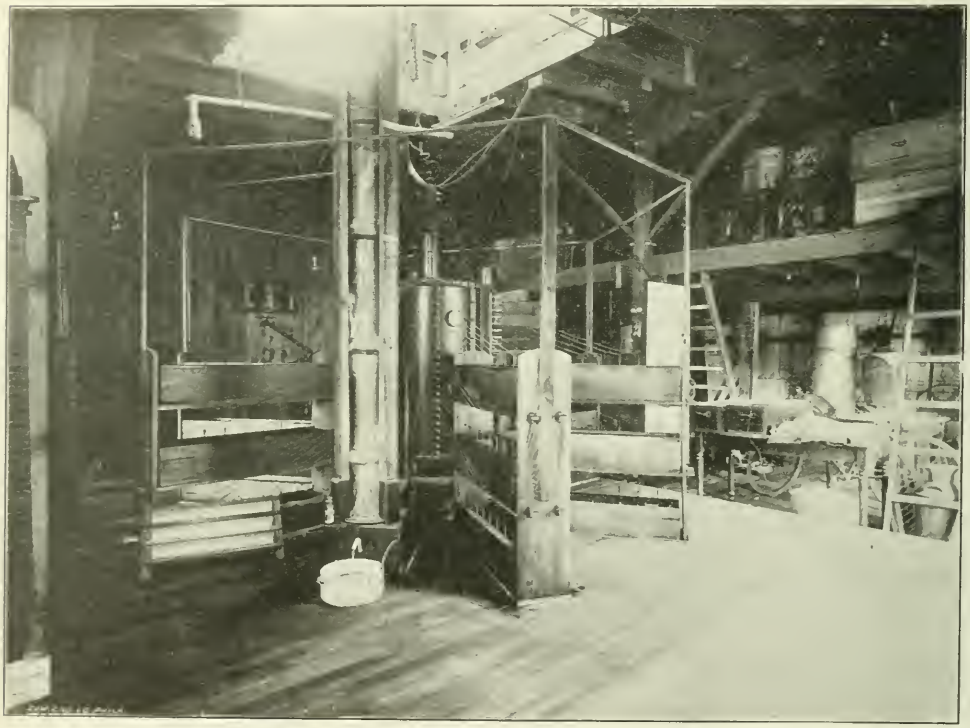

FIG. 15.—NITRIFICATION CHAMBER AND COLLECTION TOWER. THE ATMOSPHERIC PRODUCTS CO.

a manner of producing nitrogen compounds from atmospheric nitrogen, and points out that whereas the silent electric discharge and the spark or disruptive discharge can cause nitrogen and oxygen gases to combine, they have very little capacity in this respect, which is also the case with the electric arc, as ordinarily used. To obtain efficiency, it is necessary to use an arc, divided up into such small, thin, flat subdivisions as to present a large surface for a small amount of energy; the thinner the arc is the greater is its efficiency up to the point where it breaks. It is necessary, therefore, to greatly subdivide the current, to arrange the arc circuits in parallel and to provide against short circuiting.

The experimental apparatus of this company is installed at the works of the Ampère Electrochemical Co. They use a 45 kilowatt generator, ordinarily delivering 0.75 ampères direct current at a potential of 8,000 volts, but capable of giving sev-

eral ampères at as much as 15,000 volts. This remarkable generator was built by the Wayne Electric Co. The current supplies 138 arc contacts, each of which is made and broken 50 times per second, giving to each arc some 0.005 ampère. The arcs are all sprung successively, 6,000 per second in the apparatus, each arc lasting about 1-20,000 of a second, and thus giving practically a steady load to the machine. As each arc tends, the moments it is formed, to increase suddenly in

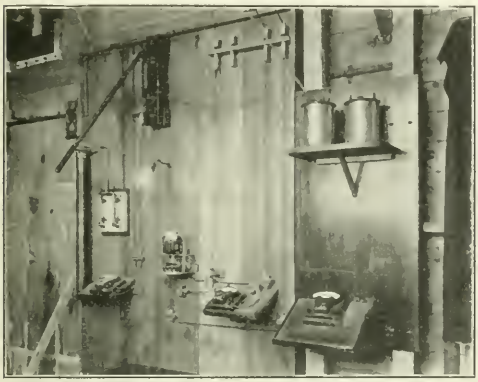

FIG. 16. SWITCHBOARD OF ELECTRICAL MEASURING INSTRUMENTS. THE ATMOSPHERIC PRODUCTS CO.

volume, the short circuiting which this would produce is retarded by placing inductance coils or resistances in series with the arcs. These are so calculated that during about 1-40,000 of a second they impede the flow of current, therefore preventing too high an ampérage flowing, and during the succeeding 1-40,000 second, while the arc is being drawn out and is about to break, it sends an impulse which increases the flow and so prolongs the arc. Using 8,000 volts, with an

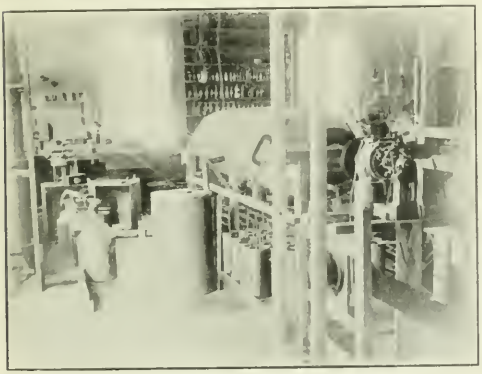

FIG. 17 EARLY EXPERIMENTAL APPARATUS. THE ATMOSPHERIC PRODUCTS CO.

average current of 1-200 of an ampère to an arc, the arcs are drawn out 4 to 6 inches. By keeping a constant flow of air into the apparatus, the per cent. of combined products in the issuing air is only 2 to 3 per cent., and much less by dissociation is thus avoided by keeping down the concentration of nitric oxides. The patent claims are for "exposure of a mixture of nitrogen and oxygen to the action of an electric arc, and renewing the mixture so as to prevent dissociation."

The apparatus used at Niagara is 5 feet high by 4 feet in diameter, circular, of iron and has in the sides six rows of inlet wires, 23 in each row, the wires entering being well insulated by a porcelain sleeve and terminating in a short

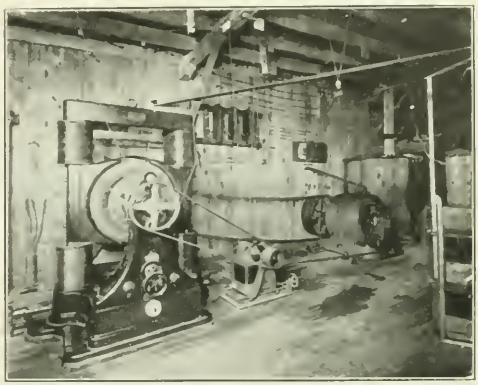

FIG. 18. MOTOR AND 10,000-VOLT DYNAMO, WITH EXCITER. THE ATMOSPHERIC PRODUCTS CO.

platinum wire, ¼ inch long, turned downwards. In the center of the apparatus is a vertical shaft, containing a series of 23 radial arms, each corresponding to the 23 rows of points.

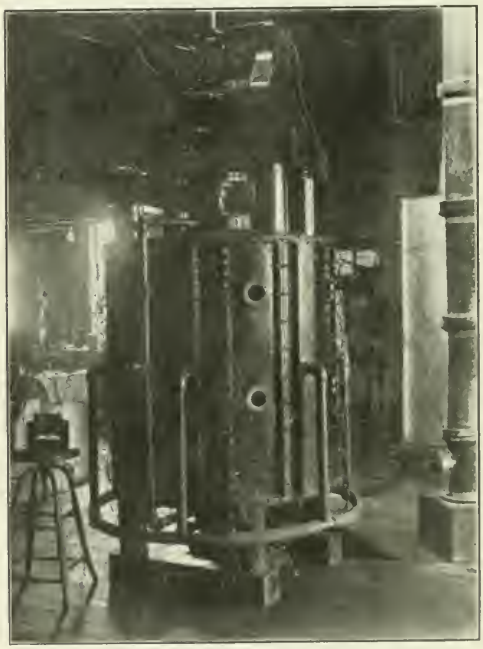

FIG. 19.—CHAMBER WITH INDUCTANCE COILS DISCONNECTED. THE ATMOSPHERIC PRODUCTS CO.

exterior wires, and there being six radial arms in each plane. The radial arms are tipped with short platinum wires, which come within 1-25 of an inch (1 millimeter) of the platinum wires of the opposite poles. As the two points approach, a

spark jump about ½ inch to meet the approaching point, and then the arc is drawn out 4 to 6 inches by the retreating point. Each arc has in series a resistance coil, 5 inches in diameter by 12 inches long, immersed in oil, and containing several thousand turns of fine wire. The central shaft is run at 500 revolutions per minute, and takes a little over 1 horse power; run at 1,000 revolutions per minute, it takes some 5 horse-power. The output is represented by one pound of theoretical HNO per 7 horse power per hour of electric current used.

Air can be used in the apparatus, first carefully dried to

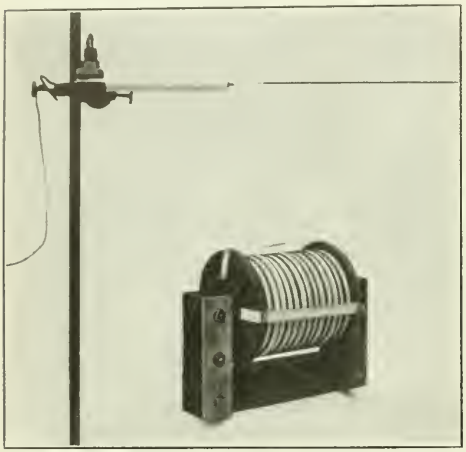

FIG. 20.—INDUCTANCE COIL AND A PAIR OF ELECTRODES. THE ATMOSPHERIC PRODUCTS CO.

avoid formation of acid in the apparatus and consequent corrosion of the metallic parts. The inside of the apparatus is protected by a coating of asphalt varnish and glass peepholes are provided, permitting inspection of the interior. A mixture containing equal parts of oxygen and nitrogen works better than air, giving a higher return for the current used. This is quite natural, since air contains 1 volume of oxygen to about 4 of nitrogen, whereas the gases formed contain 1 volume of oxygen to 1½ or 2 volumes of nitrogen. Air can be enriched to 50 per cent. oxygen in Linde machines at the rate of 1 cubic meter per horse power per hour. The efficiency obtained increases as the ampère per arc decreases, until the arc degenerates into a spark. The gases are renewed at the rate of 3 to 4 cubic feet per minute, in order that the issuing gases may not contain over 3 per cent. of nitrogen oxides. The temperature in the generator is thus kept at about 80° C. The issuing gases pass into an iron reservoir, 2 feet in diameter by 10 feet high, where they have a chance to still further combine and thence pass into a scrubbing tower to condense the gases produced. This is an earthenware pipe, 9 inches in diameter by 25 feet high, filled with coke, over which trickles water if acid is desired, or a solution of caustic alkali, if alkaline nitrate is wished. The latter is the more convenient for experimental work, as the amount of time necessary to neutralize a given quantity of alkali gives an accurate measure of the output of the apparatus. In commercial practice, water towers will be used to obtain nitric acid, for which there is a market for 100,000 tons a year in the United States, while Lunge's scrubber, supplied with milk of lime, will be used to produce calcium nitrate, for fertilizing purposes. This is a cheaper way of getting the nitrogen onto the fields than using soda, because lime costs only $1.50 per ton and is needed also by many soils.

The process has worked so successfully and promisingly on this experimental scale, that the company will engage in the commercial manufacture as soon as the power company have current to supply. It is proposed to begin with 2,000 horse-power. Since the space required for apparatus will be large, a large tract of ground, permitting future extensions, is to be acquired. Since the cost of apparatus will also be heavy, the company are already building a machine shop, 50 by 150 feet, two stories high, near to the Pittsburg Reduction Co's plant, where they will build their own apparatus. To supply all the nitric acid used in the United States would require a plant of some 150,000 horse-power, covering many acres of floor space, but such is one of the possible future developments of this process.

### THE UNION CARBIDE CO.

Calcium carbide was first made industrially by Mr. Willson, at the Willson Aluminum Works, at Spray, N. C., in 1891. Since then its manufacture has become one of the largest of the electrochemical industries, it being estimated that the total capacity of calcium carbide works in the world is 250,000 horse-power, equal to producing some 300,000 tons per year, one-fifth of which are in America.

Mr. Willson was trying to reduce lime by carbon, in the electric furnace, in order to produce calcium, with which he expected to be able to reduce aluminum. The accidental discovery that the product gave off an inflammable gas (acetylene) when brought in contact with water, and the subsequent recognition of the calcium carbide by analysis and its industrial production on a very large scale, sounds more like an interesting tale than a solid, commercial fact. It is, however, a fact that the manufacture of calcium carbide has done more to bring the electric furnace and electric methods into industrial prominence, especially in Europe, than any other electrochemical operation. In Europe, in fact, the carbide industry has been woefully overdone, Italy alone possessing enough *carbide* plants to supply the whole of Europe.

Mr. Willson's small beginnings gave place to the formation of the Union Carbide Co., which controls almost all the production in America. The works at Niagara Falls are under the management of Mr. Price, who was associated with Mr. Willson in his first experiments. The patents to Mr. Willson are U. S. Patents 541,137 and 541,138, of 1895, and 563,527, of 1896; to Mr. Price 572,312 and 572,467, of 1896, and 583,936, of

FIG. 21.—UNION CARBIDE CO.

1897. It is said that the furnaces used are covered also by the patents of Hoovey on a rotating furnace, English Patent 22,521, of 1897, although the circular furnace is said to be originally the invention of Prof. F. B. Crocker, New York.

The works are situated nearly one and a half miles from the power house, above the falls, and are supplied through a conduit with 5,000 horse-power of alternating current at 2,250 volts. The works have the option of taking up to 20,000 horse-power when they want it and the power company are

able to supply it, but the average power which has been used has been close to 5,000 horse-power. The buildings cover 200 by 880 feet of ground, the stock room being three stories in height and ten furnaces are now in operation.

The furnaces are of iron and circular, with a recessed rim, on top of which are bolted segmental wings, 24 inches deep. In the space thus created, the two carbons dip on top of the wheel, and melt the charge of lime and carbon there fed to them. The whole furnace revolves very slowly, about once in twenty-four hours, on trunnions, so that the fluid carbide resulting from the action of the arc is slowly taken out of the field and solidifies in cakes 6 to 9 inches thick, which is taken off the wheel, comparatively cold, at the lower side. The carbons are 6 inches in diameter and are kept about 9 inches apart. The furnace is 8 feet in diameter altogether, 3 feet wide and each takes 3,500 amperes at 110 volts, or 500 horse-power. The output per furnace is about two tons per day.

The materials charged are mixed burnt lime and ground coke, in the proportions of one ton of lime and three quarters of a ton of coke to produce one ton of carbide, the chemical reaction being

$$CaO + C_3 = CaC_2 + CO.$$

The temperature of formation of calcium carbide is above that of ordinary combustible-heated furnaces, but not very high in the range of electric furnace work; it is decidedly below that needed for graphitizing carbon or even for producing carborundum. If we consider the energy required to produce a ton of calcium carbide in these furnaces as 6,000 horse-power hours, we can calculate that of the total energy of the current about 45 per cent. is needed to heat the substances to the temperature of carbide formation, 40 per cent. is absorbed in the chemical reactions taking place and 15 per cent is lost by radiation during the heating (exclusive of heat in hot carbide after removal from the arc).

The ten 500 horse-power furnaces in operation will, therefore, produce 20 tons of carbide daily, using up 20 tons of lime and 15 tons of coke. The carbide, when used, furnishes theoretically 5.5 cubic feet of acetylene per pound, or actually some 5.25 cubic feet, which is 10,500 cubic feet per ton of carbide, and the 20 tons would be equal to 210,000 cubic feet, equal in illuminating power to some 2,040,000 cubic feet of ordinary illuminating gas in illuminating power. The reaction producing acetylene is

$$\underset{64}{CaC_2} + \underset{36}{H_2O} = \underset{56}{CaO} + \underset{26}{C_2H_2}$$

and since $C_2H_2$ represents one molecular volume (22.22) of gas, we may say that 64 ounces of carbide produces theoretically 22.22 cubic feet of acetylene and requiring 18 ounces of water.

## THE INFLUENCE OF DIFFUSION IN THE ELECTROLYSIS OF SODIUM CHLORIDE.

By CLINTON PAUL TOWNSEND.

THE electrolytic decomposition of sodium chloride in aqueous solution presents chemical problems of no small degree of complexity. If a body of the dissolved salt be decomposed with insoluble anodes and inert cathodes, the immediate products are chlorine and sodium, the former soluble in brine, the latter oxidized thereby, each product capable of uniting with the other, with the solvent, and with the secondary products formed by reaction of the other with the solvent. Around the anode is formed a saturated solution of chlorine, evolving the excess of gas; from the cathode hydrogen escapes, carrying upward with it and distributing through the solution the sodium hydroxide resulting from the oxidation of the metal. The sodium hydroxide and the chlorine diffuse throughout the solution, and in the regions of contact unite to form sodium hypochlorite, which in its turn diffuses toward both electrodes. At the anode it is in part oxidized to sodium chlorate, and at the cathode is quickly reduced to chloride; at both electrodes it undergoes electrolysis, the cathode products, primary and secondary, being sodium and sodium hydrate, and those of the anode hypochlorous acid and oxygen. Furthermore, not the hypochlorite only, but the chlorate and the hydroxid submit readily to electrolysis, adding to the complexity of the anode products.

Of these several products, the hydroxid, hypochlorite and chlorate of sodium, and the chlorine, are commercial articles, representing enormous aggregate values in the industrial world; still another compound, sodium perchlorate, has been produced for a hundred years past in the laboratory by electrolytic methods, but is seldom encountered in cells operating upon chloride solutions. For the production of hypochlorites and of chlorates, such disposition of parts is now employed as will facilitate the immediate combination of the products formed at the respective electrodes. For the production of caustic and of chlorine, however, the essential point is to maintain these products apart; to permit the accumulation of the caustic to a reasonable concentration, yet to prevent, so far as may be, its movement by diffusion to or into the anode solution. And surely no more interesting problem was ever offered to the experimenter. The purpose of this paper is to outline briefly, and in their broader aspects, the several lines of attack which have been opened toward a solution of the problem.

If a diaphragm be interposed between the electrodes, the course of the reactions is as above specified, for the phenomena depend largely upon diffusion, which no diaphragm permeable to the current can prevent. Yet a diaphragm modifies to a considerable extent the composition of the final products, for the convection effects, like in kind and at least equal in quantity to those due to diffusion, may be measurably overcome. The diaphragm operates, moreover, to limit the region of contact between the anode and cathode solutions, a fact which forms the basis of some very interesting and quite practicable methods for the maintenance of dilute solutions in a state of reasonable purity, by withdrawing at this point those portions of the solution which have become impure through combination.

The diaphragm may be in contact with one or both electrodes, or at a distance from either; in the latter case the cathode products are necessarily permitted to remain for long periods in contact, through the diaphragm, with those of the anode. Under these conditions diffusion is unchecked, and for this reason no cell of this type has ever attained any considerable measure of commercial success. If the cathode be moved into contact with the diaphragm, and given such open structure as will permit the ready escape through it of the products of the electrolysis, diffusion proceeds as before, but the electrical resistance is so far reduced that the line between failure and commercial success is crossed, to this type belong the earliest of the operative electrolytic processes for the production of caustic from brine. In such cells the fact of diffusion, and of losses attendant thereon, is frankly admitted, and the resulting hypochlorous acid is usually decomposed in the anode compartment by the regulated addition of hydrochloric acid, often obtained by the direct combustion of portions of the hydrogen and chlorine from the respective electrodes.

In such cells, however, the cathode compartment may be drained, and an increased efficiency is thereby secured. The cathode being in contact with the saturated diaphragm, a thoroughly efficient electrical contact is maintained, and being foraminous it permits the discharge by gravity of the excess of the percolating solution. Its capacity for retaining the caustic solution is, however, far from negligable, and in proportion as it retains such solution it fails to accomplish its proper function of a surface of discharge for the cathode products. The form of the cathode, whether a wire net, a perforated plate, a ribbed plate or a sponge, is thus an essential

pose to be determined by an experimental study of its retentive capacity. The claim more recently advanced in favor of a "spongy" or retentive cathode is that the electrolysis proceeds or continues within its interstices; admitting, however, that there exist within the body of the metal such points of potential difference with relation to the anode as will determine therein an electrolytic effect, it will require the clearest of experimental evidence to prove that the electrolyte is sodium chloride and not the more easily decomposable hydrate.

If a compact, spongy or porous, as distinguished from an open cathode, be used, the non conducting diaphragm is no longer essential to operativeness, for the cathode will itself restrain the flow of the electrolyte and permit the production of caustic of fair concentration. The retention of the diaphragm becomes then a question of expediency, its chief function being to guard the cathode from clogging by deposition therein of the hydrated oxides insoluble in the electrolyte. Seemingly, its use is advantageous, for commercial success has not been attained in its absence.

In diaphragmed cells of whatever type, a considerable apparent increase in efficiency may be secured by converting the caustic as formed into a compound less soluble in the electrolyte, more stable as regards the current or possessing a lower diffusion rate If such compound represented also an increased value as compared with the caustic and the acid radical which enter into its composition, the increase in efficiency would be real, but, unfortunately, such is not the case, and the method represents in all cases a reduction of values, and can, therefore, be regarded only as an economic retrogression. This, of course, does not mean that it may not also present a margin of profit, simply that the margin of profit is less than if the cell were so constructed as to be capable of yielding the caustic alkali. As types of auxiliary reactions of this character may be mentioned the carbonating of the cathode lyes by carbon dioxide, with the formation of the normal or acid salt; the addition of carbonates of magnesium or of zinc to form double salts; the addition of nitric, manganic and chromic acids; the employment of such solid depolarizers as the metallic sulphates, phosphates, sulphides, etc., and the use of metallic salts in solution as liquid depolarizers, examples being auric chloride, sodium plumbate and the sulphates of iron, copper and zinc. Depolarizing cathodes have also been employed; readily reducible oxides or sulphides which yield their metalloid to the liberated hydrogen. If oxides be used their reduction serves, of course, to dilute the caustic, and if sulphides, the cathode product is no longer the hydrate, but the sulphide of the alkali metal.

The cells which operate on the gravity principle, like those of the diaphragm type, are powerless to overcome the evils of diffusion. In these dependence is placed on the differences in specific gravity between a saturated solution of the salt, and the caustic and chlorine resulting from its decomposition; some devices of quite surprising efficiency have been developed here and abroad, but if it be borne in mind that the rate of diffusion is a function of the concentration of the diffusing solution, and that the amount of diffusion is a function of the time during which given solutions remain in contact, it will be readily understood that such cells necessarily yield weak caustic.

So far as concerns the yield of caustic, the use of insoluble anodes is not material, and it has been attempted to reduce the potential difference between the electrodes and to increase the total value of the final products, by the employment of depolarizing anodes. Iron, zinc, tin, lead and copper have been so used, the salts formed often being precipitated in the anode compartment, or in an external portion of the circulating system, by appropriate reagents, *e. g.*, the lead by regulated addition of soluble chromates, to prevent diffusion toward the cathode. Crude metals, as the alloys of copper and nickel, have been favorite anodes for use in these relations, and the solutions obtained are usually further treated by electrolytic methods. No process of this character has passed the experimental stage.

Or instead of using a depolarizing anode, the same result may be accomplished by adding to the anode compartment solutions to be chlorinated, or such ores as it is desired to submit to the solvent action of the anolyte. Such methods have, however, introduced such further and unexpected complications as have interfered with the smooth working of the cell.

In addition to the foregoing, two other distinctive methods have been proposed, elaborated through protean forms, and passed into commercial use. As has been pointed out, the real difficulty of the problem lies in overcoming the rapid diffusion of the hydrate through the aqueous solution, and the conception that this might be accomplished by doing away with both solution and hydrate was a basic one. New difficulties arose, however, in the attempt to produce sodium and chlorine directly from the fused chloride; hypothetical "subchlorides," formed at the high temperatures, diffuse as rapidly and with as evil effect as the hypochlorites of the aqueous solution, and for the production of the metal, compounds of lower-melting point, the hydrate and nitrate, have displaced the chloride. The employment of a liquid metal cathode to absorb the sodium as separated has proven, however, a stepping stone to success in the production of the hydrate.

As in the case of aqueous solutions the difficulty to be overcome in cells of the last-mentioned type has arisen from the diffusion into the bath of the cathode product, or, more properly, of the reduction products formed by reaction between the cation and the electrolyte; for the liberated sodium shows no tendency to distribute itself evenly through the body of the molten lead, but crusts it over in a light and rich alloy of intense chemical activity.

The problem has been doubly solved. A supplemental anode of lead, through which a fraction of the total current is shunted, has been used to determine the conjoint deposition of sodium and lead in such proportions as may be desired for the alloy. This method necessarily operates at low efficiency, not only because some 12 per cent. of the current is diverted for the solution of the lead, but because the lead chloride of the bath reacts readily with the separated sodium, the reconstituted sodium chloride representing a direct and serious loss. The second and more rational method consists in preventing the accumulation of the light metal by maintaining the cathode of molten lead in rapid circulation between the region of electrolytic activity and a separate denuding chamber, wherein the sodium is oxidized and the resulting hydrate permitted to stratify. Diffusion is here overcome by reducing the concentration of the diffusing element; the advantage is such as would be obtained in the aqueous method were it possible to remove the hydrate from the cathode at the instant of its formation. Under this mode of operation current efficiencies are high, and such concentration of plant as is indicated by the passage of a current of 19 ampères from each square inch of active anode surface offers alluring economic possibilities. All fused electrolyte methods labor, however, under the disadvantage that the separation of a gram of sodium therein, under conditions of theoretical efficiency, represents the expenditure of nearly double the energy of the same reaction occurring in aqueous solution, under conditions which permit the oxidation of the metal.

The mercury cathode method for the conversion of aqueous chloride into caustic is the precise analogue of the foregoing, and commercially is the successful method of the day. The analogy between those fused and aqueous methods which depend upon the absorption of the cation by a liquid metal is more than superficial, for not only are the methods similar in the form which they have finally taken, but in their historical development they have followed the same course. In the early work the mercury cathode was quiescent, and the objects of the electrolysis were defeated by the combination of the metal

of the light surface alloy with the electrolyte. Thereafter, the necessity for quick dissemination, or, better, for quick denudation, was recognized, and the history of recent construction in cells of this type is largely concerned with the provision of means for effecting the interchange of amalgam between the decomposing and oxidizing compartments. One additional idea has been recently introduced: the conception that means other than mechanical may control the diffusion of the sodium through the mercury. The phenomena of surface tension promise to afford a method of transmitting the alkali metal positively and rapidly through a body of mercury acting as a partition between brine and caustic solutions.

## ELECTROCHEMICAL THEORIES ILLUSTRATED BY EXAMPLES FROM PRACTICE—I.

IN this serial an attempt will be made to illustrate and explain the modern theories of electrochemical science by examples from practice, and to bring electrochemical science within the reach of the practical man. Each article will be complete in itself. In the first article we will discuss a fundamental principle of the design of galvanic cells. The following experiment, which has been described by Prof. W. Ostwald, is very instructive. Well amalgamated zinc does not dissolve in a solution of sulphuric acid. If, however, an amalgamated zinc rod in contact with a platinum wire is placed into a solution of sulphuric acid, then the zinc dissolves at once with a simultaneous development of hydrogen. Let us begin with a neutral salt solution and suspend in it a zinc rod and a platinum wire, which are in contact at one point outside of the solution; no zinc dissolves; as soon as we add free sulphuric acid the zinc begins to dissolve. Let us change the conditions slightly. Take a vessel with two compartments, which are separated from one another by a porous partition; the zinc rod is placed in the one compartment, the platinum wire in the other; the zinc and platinum are in contact outside of the vessel. Both compartments are filled with a neutral salt solution. We now wish to start the dissolution of the zinc. For this purpose we have to add free sulphuric acid to the neutral solution. Now the question arises: to which compartment have we to add the acid? At the first glance it would seem that as we wish to dissolve the zinc, we have to pour the acid into the compartment containing the zinc, but this would be wrong. By experiment we find that in order to get a lasting dissolution of zinc, we must add the acid to the compartment containing the platinum wire; the zinc dissolves in the one compartment, and at the other compartment hydrogen is developed at the platinum wire.

The explanation of the fact will give us a general principle for the design of galvanic cells. Indeed in our case, we have electrochemical action. If the ends of the zinc rod and of the platinum wire outside of the vessel are not connected directly together, but through a galvanometer, we see that a continuous current flows through the system, from the zinc to the platinum in the solution. We have here a change of chemical energy into electrical energy; in other words, we have a galvanic cell. The problem is, therefore: why is this cell active only if the acid is added to the solution at the platinum side, and not at the zinc side? The discussion of this problem will first lead us to point out the characteristic property, which distinguishes those chemical equations which can represent electrochemical action, from those which cannot represent electrochemical action. Afterwards, we will state a simple reaction which can represent electrochemical action, and will discuss the particular conditions under which, in this reaction, chemical energy is changed into useful electrical energy. We will begin with some general remarks on chemical equations.

The most concise and exact way of describing a chemical process is by means of a chemical equation. That chemical equations have a simple form, is a result of the experimental fact that elementary substances combine in constant multiple proportions. Thus, the neutralization of an acid by a base is represented by an equation like

$$HNO_3 + KOH = KNO_3 + H_2O, \qquad (1)$$

which equation states that one gram molecule $HNO_3$ (63.05 gram), and one gram molecule KOH (56.10 gram), are changed into one gram molecule $KNO_3$ (101.10 gram), and one gram molecule $H_2O$ (18.02 gram). The solution of a metal in an acid is represented by an equation like

$$Zn + H_2SO_4 = ZnSO_4 + H_2 \qquad (2)$$

which equation states that one gram molecule Zn (65.4 gram) and one gram molecule $H_2SO_4$ (98.08 gram) give one gram molecule $ZnSO_4$ (161.46 gram) and two gram atoms H (2.02 gram). This is the way in which the chemical equations are generally understood by chemists; the transformation of matter only is considered, and the combining proportions of the different materials, involved in this transformation, are given by the chemical equation.

If, however, a chemical process is considered from a broader and wider point of view, then there is not only a transformation of matter, but at the same time always a transformation of energy. If the changes of energy are taken into account, there do not exist any chemical processes pure and simple; that means: any chemical process in a system of reacting bodies (which system is supposed to be separated from the outside) represents either a gain or a loss of chemical energy in the system, and thus, according to the principle of conservation of energy, must involve a loss or a gain of some other kind of energy. The principal forms of energy into which chemical energy is changed in practice, are heat and electrical energy; one speaks, therefore, of thermochemical and of electrochemical processes.

The energy changes can also be easily represented by equations, when an additional meaning is given to the ordinary chemical symbols. Thus, $HNO_3$ represents, as before, a certain mass; if we measure all the masses in gram molecules, it represents 63.05 gram; but we now assume that it also represents a certain energy, namely, the intrinsic chemical energy stored up in 63.05 gram of the chemical compound $HNO_3$. We assume that the intrinsic energy of all the elements in the free state is zero; then the intrinsic chemical energy stored up in 63.05 gram $HNO_3$ represents the energy corresponding to the change of 1.01 gram H, 14.04 gram N, and 48 gram O, into 63.05 gram $HNO_3$. If we understand the chemical symbols in this way, the ordinary chemical equations, like (1) and (2), do not balance any more; because the chemical energy stored up in the materials at the beginning of the reaction, does not equal the chemical energy stored up in the materials at the end of the reaction. Thus, we know that when the processes (1) and (2) take place from the left side to the right side, both processes evolve energy; and if, according to our assumption, the masses of the chemical symbols represent gram molecules, then the energy evolved by each process has a certain distinct numerical value which has been determined by experiment. Energy can be measured in gram calories, watt seconds, gram centimeters, or any other unit which one may choose. The energy evolved or absorbed by a certain chemical process is generally given in gram calories, as it is determined from thermochemical measurements. The equation (1) then assumes the form

$$HNO_3 + KOH = KNO_3 + H_2O + 13{,}800 \text{ cal}., \qquad (3)$$

i. e., when in an aqueous solution one gram molecule $HNO_3$ and one gram molecule KOH change into one gram molecule $KNO_3$ and one gram molecule $H_2O$, energy is evolved equal to 13,800 gram calories. Equation (2) gets the form

$$Zn + H_2SO_4 = ZnSO_4 + H_2 + 37{,}900 \text{ cal}.,$$

i. e., when one gram molecule $H_2SO_4$ in aqueous solution dissolves one gram atom Zn, to form one gram molecule $ZnSO_4$ and 2 gram atoms H, energy is evolved equal to 37,900 gr. cal.

Instead of giving the energy value in gram calories, we

may state it, we give it in watt seconds, as there is a constant relation between both units:

1 watt second = 0.241 gram calorie,
1 gram calorie = 4.155 watt seconds,

so that it is easy to go over from gram calories to watt seconds. But the formal change from the heat unit of energy to the electrical unit is evidently useful and judicious only if we know that the chemical equation represents an electrochemical action.

Now the important question naturally arises: can any chemical equation represent an electrochemical action? It will be shown that this question must be answered in the negative. For instance, it will be shown that of the above chemical reactions, both of which evolve energy—equation (1) can never by itself represent an electrochemical action, while equation (2) can represent an electrochemical action. What, then, is the characteristic feature of those chemical equations which can represent electrochemical action?

We know that whenever electrochemical action takes place either in a cell into which current is sent from the outside, or in a galvanic cell, which gives out current—the strictly electrochemical action takes place at the electrodes. We may say in general that we have always reduction at the cathode and oxidation or perduction at the anode. The term "perduction" has recently been suggested by J. W. Richards, instead of oxidation, because the latter term would seem to indicate a combination with oxygen, which is not always the case when we have perduction. The characteristic feature of reduction and oxidation, or perduction, is that there is a change of valency. The amount of material reduced at the cathode and the amount of material oxidized or perduced at the anode are directly given by Faraday's law; and as the latter is the fundamental law of electrochemical action it is evident that there must be reduction and oxidation, whenever there is electrochemical action. In the experiment described above, zinc goes into the solution; from the uncombined state it goes over into the sulphate, it gains "bonds," in other words it is "oxidized," or perduced. At the other end, at the platinum wire, hydrogen leaves the solution; from the state of combination with $SO_4$ it goes over into the uncombined gaseous state, it loses "bonds," in other words, it is reduced. This example will show what is meant here with reduction and oxidation; a more detailed discussion of this matter will be given in a future article. For the present it is sufficient to state that only those chemical equations can represent electrochemical action which represent oxidation and reduction. This is the case for equation (2), as just explained, but it is not the case for equation (1). In equation (1) H and K simply exchange their places, but *without any change of valency*. For this reason it is evident that under no circumstances equation (1) by itself can represent electrochemical action; of course, the process represented by (1) may take place as *part* of the whole process occurring in an electrochemical system, but it can never represent the total electrochemical process.

Now take the reaction of equation (2). We know it can represent electrochemical action. But this does not mean that under all circumstances we get the chemical energy lost during this reaction in the form of useful electrical energy. For instance, when we put unamalgamated zinc into sulphuric acid, equation (2) again represents the action, but in this case we get heat instead of electrical energy. It is evident that to change the chemical energy into useful electrical energy, we must arrange our system properly; and this leads us back to Ostwald's experiment described above. We saw that in the arrangement described it was necessary to add the acid to the compartment at the platinum wire. The reason will now become clear: we always must arrange our system so that the substance to be reduced is at the one electrode and the substance to be oxidized is at the other electrode. If we bring both substances together directly, the chemical energy is changed into heat. If we want to get useful electrical energy, we have to keep them separated, and have to place the substance to be reduced at the one electrode, and the substance to be oxidized at the other electrode. That is why Ostwald speaks of "chemical action into the distance." In our case, while the cell gives out current, zinc is dissolved, *i. e.*, oxidized, and hydrogen is reduced from its combination in $H_2SO_4$ to free hydrogen. Hence the sulphuric acid must be placed at the platinum.

This principle appears now to be self-evident, but it has not always been so, and many inventors, in designing batteries, have made the mistake of bringing the substances to be oxidized and to be reduced directly together; the result is always in such cases that a strong chemical action occurs, but that heat is developed instead of electrical energy.

We will briefly illustrate our principle by a few examples. In the Daniell cell we have the reaction

$$Zn + CuSO_4 = ZnSO_4 + Cu;$$

Zn is oxidized, Cu is reduced. The Zn and $CuSO_4$ must be kept separately; this is done by using a double fluid cell, the Zn being placed in a solution of $ZnSO_4$ or $H_2SO_4$.

In the Bunsen cell, with Zn in $H_2SO_4$, and C in $HNO_3$, Zn is oxidized and N is reduced; hence the Zn and $HNO_3$ are kept separately; one of the possible reactions is

$$3\,Zn + 3\,H_2SO_4 + 2\,HNO_3 = 3\,ZnSO_4 + 2\,NO + 4\,H_2O.$$

In the same way, in the chromic acid battery we must keep the chromium solution away from the zinc.

In the lead accumulator the action is

$$Pb + 2\,H_2SO_4 + PbO_2 = 2\,PbSO_4 + 2\,H_2O,$$

the spongy lead at the one side being oxidized to lead sulphate, and the lead peroxide being reduced to lead sulphate at the other side.

In the new Edison battery we have the reaction

$$NiO_2 + Fe = NiO + FeO,$$

the nickel being reduced and the iron oxidized.

Everything in Ostwald's experiment, which seemed peculiar, can now be explained. Amalgamated zinc does not dissolve in a solution of sulphuric acid; it represents a single electrode, and this is no electrochemical system. But if this zinc is in contact with a platinum wire, we have an electrochemical system, we have a short-circuited cell, hence the zinc will dissolve. If we use the vessel with the two compartments separated by a porous partition, then one compartment will have to represent the anodic compartment, and the other the cathodic compartment; in the former we have to place the zinc, which is to be oxidized, and in the latter the acid, as the hydrogen is to be reduced. The neutral salt solution around the zinc furnishes the ionic mechanism by which the "chemical action into the distance," *i. e.*, the reduction and oxidation at both ends, is made possible.

## GRAPHITE ELECTRODES IN ELECTROLYTIC WORK.

By C. L. Collins, 2D.

THE relative value of graphite and other forms of electrode material in the various lines of electrolytic work has already been discussed thoroughly, and the results of numerous comparative tests published. These results, obtained both in experimental test and actual practical work, may be briefly summarized as follows:

In the electrolytic decomposition of chloride solutions, in the manufacture of chlorine and caustic alkalies, in the chlorination of gold ores, in the recovery of nickel, zinc, etc., graphite electrodes used as anodes possess a life from two to four times as great as that of the best crude-retort carbons, and from four to seven times that of the various makes of manufactured amorphous carbons, such as those made from mixtures of a pitch bond and powdered petroleum coke or lampblack, etc. In consequence, the graphite electrodes are rapidly replacing all such forms in this line of work, and are even

proving more efficient and economical than platinum, on account of the excessive cost of the latter material. In electrolytic processes, however, where the anode is subjected to a more active oxidizing action, such as in the manufacture of chlorates, the deposition of metals from sulphate solutions, in the oxidation of chromic acid solutions, etc., the differences between the action of graphite and amorphous carbon, although still very much in favor of the former, are not so great, and both suffer considerable disintegration. In chlorate work platinum and platinum-iridium alloys are still extensively used as anodes.

In alkaline-cyanide solutions, in the recovery of gold and silver from its ores, iron anodes have generally been used, and in some cases platinum; but serious corrosion with the former, and the expense of the latter, have been decidedly disadvantageous. Here also the graphite electrode is proving successful. Although there is a slight coloring of the solutions with such electrodes, absolutely no corrosion is apparent, and with the proper current densities there is very little disintegration. The coloring of the solution prevents the use of graphite electrodes in electroplating with gold or silver in cyanide solutions, as here the deposited surface must be seen and examined during the operation, but in processes for the recovery of metals from their ores this element need not be taken into consideration.

The processes mentioned above represent the largest fields of electrolytic work in which graphite electrodes are now being used; but actual comparative tests which are being made in other and newer lines of work continually prove that the value and usefulness of this material to the electrochemical industry is still to be fully appreciated. All tests to which graphite has been subjected, however, have dealt purely with its chemical properties, or its ability to withstand, for a longer or shorter period, in comparison with other materials, the action of certain electrolytes. The results thus obtained do not in themselves give a true basis for comparison, for the ease with which graphite can be handled, its *adaptability*, purity, high electrical conductivity and other *physical* characteristics, should be given equal consideration. It is conceivable that these latter might in certain processes more than offset the single advantage of longer life possessed by some other form of electrode material.

Graphite electrodes can be machined with the greatest ease, and it is to touch upon this characteristic, and the consequent adaptability of graphite electrodes to almost any conditions, that this paper is written. Ease of machining, however, can be said to apply only to electrodes manufactured by the Acheson process. With this process all electrochemists are familiar, and a description of the method of graphitizing employed is unnecessary.

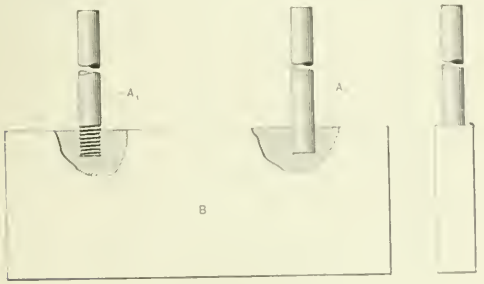

FIG. 1. GRAPHITE ELECTRODE.

In electrolytic work the size and shape of the electrode is determined more in reference to a certain surface area desired than to the cross section necessary to carry the total current used. For mechanical strength the electrode must be given a fair thickness, in proportion to its width, and with the low current densities of practical electrolytic work, the carrying capacity of its cross section is never approached. It is, therefore, of importance to design an electrode which will give a large surface area, with a minimum volume, and whose surface area will not decrease appreciably as slow, gradual disintegration takes place, assuring fairly uniform current densities. The ease of machining graphite electrodes, or their extreme adaptability, makes such forms possible.

In Fig. 1 is shown a form of anode consisting of a graphite slab *b*, into one edge of which are fitted graphite rods $a_1$, $a_2$, etc. These *leading-in* rods can be as many, or as few, as desired, and are designed to utilize the full electrical conductivity of graphite articles. They serve both as means of support for, and as the electrical conductors to, the slab *b*, or anode proper. The rods may either be threaded into the slab as $a_1$, or both the rod and the hole in the slab may be given a slight taper and a tight, drive fit made as in $a_2$. In Fig. 2 the slab is shown suspended vertically in the electrolyte.

FIG. 2. GRAPHITE ELECTRODE.

If a slab is used alone as anode, especially in cells which it is desired to keep tight for the collection of some liberated gas, as in chlorine work, connection must either be made by casting some form of metal head, unaffected by the gas in question, on the end of the slab, or, the slab must be brought through the cover of the cell and connection made with the metal conductors outside. In either case there is unnecessary electrode weight above the surface of the electrolyte, to be thrown away when the anode has been used. Furthermore, in the one case corrosion is apt to take place in the contact between the cast head and the slab, and in the other it is not always easy to make a perfectly tight seal around a slab of any size where it passes through the cover of the cell, and, consequently, some gases escape.

In the arrangement shown in Fig. 1, practically all of the main weight of the anode is active surface; the rods can be used over again; there is absolutely no deterioration of contact between the rods and slab, nor is there any difficulty in making a tight seal around the small rods where they pass through the cover of the cell. With the slow, gradual disintegration of the slab *b*, its surface remains fairly constant. To prevent any creeping of solution up through the rods or a possible escape of gases through the same, which might act on the metal conductors, the rods can be impregnated with paraffine.

If for any reason it is absolutely essential that connection with the metal conductors be made inside the cell, instead of casting a metal head to the end of the electrode, which must be re-cast every time the electrode is removed, a round graphite electrode can be used, which can be threaded on the end and screwed into a tapped hole made in the cast head. Electrodes can then simply be screwed into the same cast head as it becomes necessary to renew them.

The methods mentioned above have already proved very successful in actual electrolytic work upon a practical scale. Other forms even more complex are being used, which would have been wholly impossible with the old style of amorphous carbon electrodes. Although the style of anode shown is the simplest possible form, and is applicable to practically any process, special conditions might require other methods of machining and assembling. It is hoped, however, that with the above practical illustrations, other forms will suggest themselves which may be the most suited to the special work of the experimenter in question.

# ANALYSIS OF CURRENT ELECTROCHEMICAL PATENTS.

UNITED STATES PATENTS ISSUED JULY 1, 1902.

**No. 703,420.** Filed August 1, 1899; Rudolph M. Hunter, Philadelphia, Pa. Process of making accumulator plates.

The inventor casts a lead framework around segments of coiled or folded strips of lead, which he cools during the process with a stream of air, claiming to produce a "mechanically integral structure." To really accomplish this object would require not only the actual fusion of the segment of coiled lead at the points of union, but also either a flux or reducing agent to remove the film of lead oxide that is inevitably present. The wording of the specification indicates that the inventor does not intend to actually fuse the edges of the strips. It seems doubtful whether this method can compare favorably in cheapness with many of the well-known methods of making (by rolling or punching a plate), which consists of an integral structure of ribs and thin laminæ.

**No. 703,490.** Filed July 13, 1891; Malcon O. Smith, Depew, N. Y. Storage battery.

This battery consists of a cup-shaped cell of lead, the outside of which forms one pole and the inside the other pole. The form is adapted for the piling up of several cells in series and is very similar to that of G. Philippart, patented January 29, 1884 (No. 292,762).

**No. 703,541.** Filed January 22, 1891; C. C. Clark, Philadelphia, Pa. Water purifier.

An electrolytic tank inserted within a larger settling tank. Water is admitted through the electrolytic tank, where it is electrolyzed between perforated copper, platinum or iron electrodes; thence it passes into the settling tank. The settling tank is provided with tubes for cooling or heating, as the case may require, and with a dome for the collection and elimination of gases and lighter impurities. Details of construction.

**No. 703,623.** Filed June 26, 1891; Theodore F. Taylor, Camden, N. J. Electroplating apparatus.

Details of construction are claimed for a rotable drum, in which small articles are tumbled and plated simultaneously. There is a fixed anode and a cathode of revolving rings.

**No. 703,673 and 703,674.** Filed September 13, 1899; Elmer A. Sperry, Cleveland, Ohio. Assignee, National Battery Co. Electric battery and mounting same. Connection for batteries. Mechanical construction of battery jar or receptacle.

**No. 703,857.** Filed August 6, 1891; C. J. Tossizza, Paris, France. Electrometallurgical treatment of zinc ores and especially blend.

This patent is to provide a method for depositing zinc from solution by the joint action of electrolysis and a chemical reducing agent. The reagent employed is sulphurous acid. In order to prevent the reduction of sulphurous acid to sulphur or hydrogen sulphide, he makes two separate operations; one operation in which copper is dissolved and zinc deposited, the e. m. f. being 2.30 — 1.21 = 1.09 volts; the other operation in which copper is redeposited and $SO_2$ oxidized to $SO_3$. It is claimed that the two operations combined require only from 1.4 to 2 volts.

Such a double cycle has certain disadvantages. One which would be practically very great, is the introduction of copper into the electrolyte without contaminating the deposited zinc. The patentee does not state whether he prevents this by porous diaphragms or in any other way.

**No. 703,861.** Filed March 5, 1891; A. A. Vogelsang, Dresden, Germany. Electrolytic cell and electrode therefor.

"The object of the invention," as stated by the inventor, "is primarily to enable all-platinum electrodes to be used economically." Parallel electrodes of platinum foil, not connected to any source of current except the electrolyte, are so disposed in a trough that the electrode flows in a zigzag path over one and under the next from one end of the trough to the other. The terminal electrodes only are connected to a source of current. A portion, at least, of the current will evidently traverse the solution from end to end, entering and leaving only the terminal electrodes. Whether the total current will take this path or a part of it go through the suspended intermediate electrodes will depend on the electromotive force employed and the nature of the electrolyte.

**No. 703,875.** Filed March 14, 1901; Walter E. Winship, San Francisco, Cal. Active material for storage batteries and process of making same.

Lead oxides are mixed with water and glycerine into a paste, which sets quickly and firmly. This is reduced to spongy lead electrolytically in a bath of a fixed alkali carbonate. It is claimed that the slight solubility of the paste in the alkali carbonate causes the lead to "tree" in parallel crystals and form a mass of greater porosity and other desirable properties. It seems that some of the claims would cover broadly the well-known process of reducing lead chloride to metallic lead electrolytically, as for example, claim 1: "The process of forming an active material for storage batteries consisting in suitably binding a mass of lead salt which will retain its configuration after immersion, and reducing it by electrolysis to spongy lead in an electrolyte which is a solvent for the lead salt, and from which solution lead trees essentially parallel to each other are plated within the mass."

**No. 703,895.** Filed October 18, 1900; A. F. Clark, Philadelphia, Pa. Separator plate for secondary batteries.

The separator plate consists of hard rubber in the general form of a window blind with outwardly and upwardly projecting slats, forming pockets with the adjacent face of the positive plate, in which active material is retained and prevented from falling to the bottom of the cell.

UNITED STATES PATENTS ISSUED JULY 8, 1902.

**No. 704,010.** Filed May 23, 1898; Thomas A. Edison, Llewellyn Park, N. J. Apparatus for concentrating magnetic iron ores.

This is a combination of pulverizing rolls, screens, drums, magnetic separators and conveyors.

**No. 704,125.** Filed July 20, 1891; W. T. Seddon, Minersville, Pa. Battery.

Mechanical details of structure of a battery consisting of zinc and carbon electrodes, the carbon electrodes being hollow and containing "chrome salt solution." No electrolyte is mentioned except the "chrome-salt solution."

**No. 704,252.** Filed July 30, 1901; Henry K. Hess, Philadelphia, Pa. Process of making plates for storage batteries and product thereof.

Active material is molded into the form of a plate and at the same time molded around the conducting metal strips by means of pressure. Details of the mold are described.

**No. 704,303.** Filed January 8, 1901; Thomas A. Edison, Llewellyn Park, N. J. Reversible galvanic battery.

This battery comprises an oxide of mercury anode and a cathode of zinc, deposited upon metallic magnesium, the electrolyte being an alkaline solution. The oxide of mercury is mixed with flake graphite and confined in a perforated nickel receptacle. The general construction of this receptacle has been described by the inventor in previous patents, particularly in an application filed October 31, 1900. The advantage claimed for oxide of mercury is that no particles of the oxide, when reduced and in contact with the zinc, produce local action.

They merely amalgamate the zinc instead of producing local action. In this connection the inventor says: "with almost every other oxygen-storing element of which I have knowledge, infinitesimal amounts thereof are dissolved in the alkaline solution and produce objectionable local action on the zinc."

The use of metallic magnesium, on which zinc is deposited, as an accumulator plate, is singular, as it would seem that the highly electropositive properties of magnesium render it extremely liable to oxidation. This is particularly true when it is amalgamated; an amalgamated strip of magnesium in contact with pure water is rapidly converted into magnesium hydrate with the evolution of hydrogen gas. The use of oxide of mercury as a positive element instead of lead peroxide, requires about the same weight of material for a given capacity in ampere hours.

**No. 704,304.** Filed March 1, 1901; Thomas A. Edison, Llewellyn Park, N. J. Reversible galvanic battery.

The object of this patent is to claim specifically oxide of cobalt ($Co_2O_3$) as a depolarizer in an alkaline reversible galvanic battery. The oxide of cobalt is mixed with graphite or other flake-like conducting substances. Oxide hydrate or dioxide of cobalt is prepared in the usual way by precipitation. After drying, powdering and pulverizing very finely, it is mixed with one-seventh of its weight of graphite. Finely divided iron is mentioned as the negative plate.

**No. 704,305.** Filed May 17, 1901; Thomas A. Edison, Llewellyn Park, N. J. Electrode for storage batteries.

Claims a receptacle for active material for a storage battery, comprising a pocket of perforated and corrugated metal with a support for the same. It is found necessary in a battery of the iron-nickel-alkaline type to retain the active material in close contact by means of pressure with the conducting support. Perforated metallic cases or pockets of very thin sheet steel, plated with nickel, have not sufficient rigidity to maintain an intimate contact by pressure under the influence of expansion and contraction due to charging and discharging. By corrugating the perforated metal, however, the rigidity of the receptacle is greatly increased, as well as the amount of expansion it will undergo without exceeding the limit of elasticity.

**No. 704,306.** Filed July 20, 1901; Thomas A. Edison, Llewellyn Park, N. J. Reversible galvanic battery.

The claims cover specifically the combination of finely-divided copper negative plate and nickel or cobalt oxide mixed with flake graphite as a positive plate in an alkaline solution. The construction is substantially the same as the Edison nickel-iron battery with the substitution of finely-divided copper for the iron. It is stated that oxide of cobalt is not as desirable for this use as oxide of nickel, "owing to the greater cost and to the fact that it is slightly soluble in the alkaline electrolyte." Both active materials are intimately mixed with an inert flake-like conducting substance, such as flake graphite, to increase the conductivity of the cell. Pure carbonate of copper is reduced by hydrogen at the lowest possible temperature, not exceeding 500° Fahrenheit for six or seven hours, until the copper is converted into its black oxide. The inventor states that unless the copper is in a very finely-divided form throughout, a soluble blue salt is produced, which results in local action and rapid deterioration of the elements. The nickel hydrate is prepared in a non-colloidal form by adding to a boiling solution of nitrate of nickel a sufficient quantity of magnesium hydroxide to precipitate the nickel as hydroxide.

**No. 704,349.** Filed March 15, 1901; Eugene Lecomte, Estaires, and Jerome Loiselet, Paris, France. Process of manufacturing rice starch or other amylaceous substances.

The rice or other grain, after washing and soaking in a dilute alkaline solution, and after being finally washed with pure water, is ground into a paste, diluted and rendered alkaline by sodium carbonate to the extent of one gram of soda per liter. The object of the sodium carbonate is to produce electric conductivity and to assist in removing the gluten. The solution is then electrolyzed in tanks with "electrodes of aluminum, zinc or any other suitable matter." The action of the current precipitates gluten and other organic matters, leaving the starch practically pure.

**No. 704,393.** Filed February 27, 1901; Albert Simon, Bordeaux, France. Manufacture of iron, manganese and alloys of these metals by aid of electricity.

The material is dissolved in fused calcium fluoride in an electric furnace of special construction. The iron, manganese or alloy is deposited electrolytically on the cathode by a continuous current. The inventor states that the "silicon reduced under the action of the current combines with the free fluorine to form the gaseous fluoride, which is set free, so that the metal only retains but small quantities of silicon." How the fluorine set free at the anode combines with the silicon liberated at the cathode, thus chemically removing the reduced silicon from the reduced iron or manganese, is not explained by the inventor.

**No. 704,399.** Filed December 16, 1895; Julius Taluau, Philadelphia, Pa. Stained glass window or similar object, and process of making same.

**No. 704,400.** Filed June 30, 1897; Julius Taluau, Philadelphia, Pa. Method of framing glass.

**No. 704,401.** Filed March 22, 1898; Julius Taluau, Philadelphia, Pa. Method of framing glass.

These three patents all relate to improved methods of uniting small pieces of glass into an ornamental framed plate. Plates of this kind have heretofore been made by running strips of lead between the adjacent pieces of glass and soldering at the joints. By the electrolytic process the pieces of glass are laid upon a conductor, such as a sheet of lead with spaces between for the electrodeposition of copper. The pieces of glass may be fixed in place by means of wax. The plate is then placed in a bath of copper sulphate as a cathode, the deposited copper filling the spaces between the pieces of glass and uniting the whole into a rigid substantial frame. By this process the most intricate designs composed of very small pieces may be united at very little expense.

### UNITED STATES PATENTS ISSUED JULY 15, 1902.

**No. 704,639.** Filed September 27, 1899; Carl Hoepfner, Frankfort-on-the-Main, Germany; Henry Orth, Jr., administrator. Leaching and extraction of metals from their ores.

The improvement covered by this patent over previous processes of Hoepfner for extracting copper from sulphide and other ores, consists in the use of a solution of cupric chloride in a non-saturated solution of sodium chloride. Instead of the quantity of chloride of sodium which would saturate the solution the inventor uses from one-quarter to three-quarters of that quantity. He finds that cupric chloride solutions containing less than the saturating quantity of chloride of alkali or alkaline earth metals can be made more concentrated in cupric chloride. When heated to from 60° to 100° C. these solutions are very active solvents of copper, copper sulphide, silver and other associated metals with formation of cuprous chloride, also of cuprous chloride, lead chloride or silver chloride, which are rendered partially insoluble by cooling, thus offering a very easy means of separating these salts.

**No. 704,640.** Filed June 25, 1895, and October 30, 1901; Hudson Maxim, Brooklyn, N. Y. Electrical furnace for treating highly refractory substances.

A special form of rotating horizontal tubular electrical furnace, having a screw feed for forcing the material to be operated upon into the furnace at one end and out at the opposite end. A peculiar feature of this furnace is a fused lining of material, having greater specific gravity than that of the material treated. This fluid lining is maintained by cen-

trifugal force in its position in the form of a liquid tube surrounding the material to be operated upon. The furnace is intended particularly for the production of calcium carbide.

**No. 704,675.** Filed July 27, 1901; David H. Browne, Cleveland, Ohio, and Thomas M. Niel, Toronto, Can. Process of recovering metallic tin.

Scrap tin and ores of tin are treated with a solution of ferric chloride, heated and slightly acidulated. The tin is dissolved and the ferric chloride reduced to ferrous chloride. The second step in the process is the deposition of the tin electrolytically from the solution at the cathode and the reoxidizing of the ferrous chloride to ferric chloride at the anode. A porous diaphragm is used to separate the analyte from the catholyte. The solution is first used as a catholyte, from which the tin is deposited, leaving iron as ferrous chloride. This solution then becomes the anolyte and is reoxidized to ferric chloride.

**No. 704,739.** Filed October 3, 1900; J. B. Entz, Philadelphia, Pa. Secondary battery.

The object is to produce a lighter accumulator for automobiles. A special form of corrugated grid of antimonial lead provided with projections or perforations for holding the active material is employed. The plate is constructed of rolled antimonious lead, which, it is claimed, becomes malleable by reason of the rolling. Eight per cent. of antimony is recommended. This material does not oxidize under the action of the battery and is, therefore, durable, "retaining its initial strength during the existence of the plate."

**No. 704,744.** Filed April 28, 1902; Herman Heinicke, Schoeneberg, near Berlin, Germany. Electric accumulator.

A special form of grid or support for the active material, consisting of a conducting base with angular grooves extending from top to bottom and horizontal strips which assist in retaining the active material.

**No. 704,751.** Filed July 30, 1901; Harold M. Martin, Philadelphia, Pa. Manufacture of secondary-battery plates of the Planté type.

This patent claims broadly the process of rapidly forming a storage-battery plate by electrochemical means and controlling the temperature, particularly by keeping the temperature of the electrolyte below 115 Fahrenheit. This is done "by abstracting heat from it" when its temperature increases. There are many processes in common use for forming active material electrochemically which generate heat and cause an increase of temperature. The abstraction of heat seems to be the only possible way of keeping the temperature down and is the method always used. The novelty of such a process as cooling an electrolyte by abstracting heat from it is not apparent.

**No. 70,4759.** Filed July 29, 1901; Hugh Rodman, Philadelphia, Pa. Storage-battery separator.

The combination of storage-battery plates with an imperforate wooden diaphragm between each pair of plates, said diaphragm having acid wells both sides thereof in a substantially vertical position. The object of this separator is to provide a free circulation of the acid from the top to the bottom through vertical grooves or wells cut on the sides of a wooden sheet. These grooves may be parallel on both sides or those on one side may cross grooves on the opposite sides at a small angle. The latter arrangement would probably give greater stiffness and durability. Any kind of wood may be used, but porous or fibrous wood is particularly recommended. It is stated that diaphragms of wood possess unique and remarkable properties which adapt it for the purposes. The remarkable properties mentioned are efficiency, durability and capacity.

**No. 704,767.** Filed September 20, 1900; Edward G. Steinmetz, Philadelphia, Pa. Secondary battery.

The object of this invention is to avoid the casting of lead chloride and its detrimental effect upon the health of the workmen, also to avoid the production of blow holes. A crystalline structure is imparted by subjecting the mass of lead oxide or lead salts to electrolytic action in a bath capable of dissolving it, the salt or oxide going into the solution and immediately re-depositing it in a metallic state of crystalline structure, without any substantial change of external form of the mass. The material is first molded or stamped into blocks or cakes. A lead grid is cast around these cakes in the usual manner. The plate is then used as a cathode in an electrolyte, in which the lead salt or compound is insoluble. The improvement consists in stamping or molding the material instead of casting it into cakes or blocks. In all other respects the process and results are identical with others in use; such, for example, as the well-known "chloride" battery plate, the cast-lead chloride being soluble, as well as the molded.

**No. 704,831.** Filed June 1, 1901; Charles B. Jacobs, East Orange, N. J. Process of manufacturing sulphuric acid from sulphur dioxide in aqueous solutions by electrolysis.

Claims the process of making sulphuric acid by passing sulphur dioxide through a porous anode and setting free the oxygen of water upon said anode. A horizontal porous conducting plate, cemented into a jar, forms a partition dividing the upper part of the jar from the lower. Sulphur dioxide is admitted below this partition and is caused to pass through the pores into the upper chamber containing sulphuric acid. The temperature is maintained by refrigeration at zero centigrade, in order to secure a concentrated solution of sulphur dioxide. Strong acid is produced and is drawn off when it reaches the proper strength, as indicated by a hydrometer. A pressure of 2 volts and a current density of 15 to 20 ampères per square foot anode surface is used. The inventor states that 500 ampères will produce one ton of 50° Baumé sulphuric acid in three hundred and three hours, with a theoretical efficiency of 54 per cent. There seems to be some mistake here, as this quantity of electricity would produce only 203 kilograms or 450 pounds of concentrated sulphuric acid, while one ton of 50° Baumé acid would contain 1,240 pounds of the concentrated acid. Pure $SO_2$ is obtained by saturating water with the gas at the freezing point, under which condition $H_2SO_3$, $14H_2O$ are separated, leaving the impurities of the gas behind.

**No. 704,850.** Filed November 21, 1901; Victor Cheval and Joseph Lindeman, Brussels, Belgium. Electric accumulator-electrode.

A form of construction in which the negative plate consists of a single mass, having vertical cylindrical or prismatical holes, into which a number of positive electrodes in the form of rods are inserted.

**No. 704,903.** Filed January 8, 1900, and May 16, 1902; Frederick C. Weber, Chicago, Ill. Electric smelting furnace.

A vertical tubular furnace, having numerous electrodes in the form of rods arranged radially and adapted to produce ares within the tubular furnace chamber of varying intensity at different points and subject to regulation.

### United States Patents Issued July 22, 1902.

**No. 705,076.** Filed February 19, 1902; Charles M. Hall, Niagara Falls, N. Y. Manufacture of carbon electrodes.

A furnace for baking carbon electrodes, particularly such as are to be used for the electrolysis of fused baths. The carbons are placed in proximity to an electrically-heated carbon core and insulated therefrom, the object being to prevent as much as possible of the current from passing through the carbons themselves and to develop the heat in the carbons gradually by radiation. It is claimed that carbons thus produced are of greatly improved quality.

[*Lack of space requires that several patents issued in July be reserved for the next issue.*]

# SYNOPSIS OF ARTICLES IN OTHER JOURNALS.

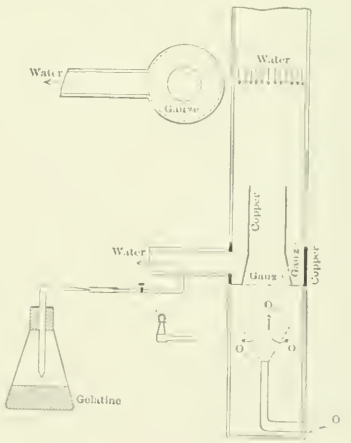
*A Summary of all Articles on Electrochemistry and Allied Subjects Appearing in American and Foreign Periodicals.*

BY CARL HERING.

## INDUSTRIAL ELECTROCHEMISTRY.

*Metal Refining.*—A good process may readily be a commercial failure if it is not properly carried out from the industrial standpoint, while, on the other hand, a poor process may sometimes, by good design of the installation and good management, be made a commercial success. As so much depends on the proper design and arrangement of such installations, an article by PHILIP, begun in the Lond. *Elec.*, August 1st, and containing many statistics and formulas, will, no doubt, be of interest to those who have the responsibility of designing plants for electrolytic metal refining, as he has for many years past collected and tabulated all the available details of such installations, in order to elaborate a connected scheme by means of which the task of designing an electrolytic refinery upon a sound financial basis might be successfully undertaken. The general method which he adopted was to endeavor to arrive at a formula for every item of outlay, expressing it in terms of all the variables involved, and then to insert in this a constant or constants obtained by calculation from all the available and trustworthy figures hitherto published with regard to the particular item of outlay under consideration. For instance, the power employed in an electrolytic copper refinery must vary directly with the number of tons output per year, when the current density is kept constant; while, on the other hand, if the output is kept constant, then if the current density is doubled (neglecting the back e. m. f. at the electrodes, which is small and constant) the voltage must also be doubled, while only half the total number of vats will be used; hence the power required must be doubled. He thus arrives at a formula stating that the cost of the power plant must be proportional to the product of the annual output of refined copper and the current density. This, of course, applies only to such cases in which the counter e. m. f. may be neglected. He then takes up in detail the problems of the establishment of an electrolytic copper refinery. The first point is the amount of capital available, the other important points are current density, area of ground, tons of copper to be refined per year and profit available per year; the current density is always the ruling factor. Taking up first the capital expenditure, the cost of offices in pounds sterling is given as 150 + 1-10 the number of tons refined per year. The area of refinery buildings for a given yearly output is inversely proportional to the current density; the area in square feet is given as 30 times the ratio of the number of tons refined per year to the current density in ampères per square foot; the constant 30 is an average value, in six different plants it varied between 21.9 and 31.5. The cost of the buildings in pounds sterling is given as 7.5 times the ratio of the output in tons per year to the current density in ampères per square foot. The power required varies directly as the output per year and also directly as the current density employed. If gas engines with gas producer plant are installed, and if the prime cost of supply and erection of this plant is $80 per horse-power installed, then the prime cost of the plant in pounds sterling, including the erection of gas engine and producer plant, may be fairly given as 0.12 times the product of the output in tons per year and the current density in ampères per square foot.

*Sterilizing Water by Ozone.*—That ozone is a powerful destroyer of organic matter, be it vegetable or animal, is as well known as the fact that most drinking waters need sterilization. The question, therefore, is not whether water can be sterilized with ozone, but it is to show that it can really be carried out effectively at a cost which is not prohibitive; it is, therefore, a question which can be decided only in actual practice on a large scale. If ozone could be generated at anything approaching the theoretical efficiency, the problem would probably be a comparatively easy one, but even the best ozone generators are horribly inefficient, as they generate only a few per cent. of the amount of ozone which corresponds to the energy consumed. There are other practical difficulties, such as getting the gaseous ozone in contact with each of the particles of such enormous quantities of water as are used in a city. Many systems have been proposed and some have been tried, but few have survived. The Vosmaer-Lebret system, however, seems to have stood a fair trial, as it has been used commercially in Schiedam and later in Nieuwersluis, near Amsterdam. In the former city it was used for eleven hours per day during two periods of six months, without any interruption, which speaks well for it. A description of this process was recently given in a Bunsen Society paper by H. J. VAN'T HOFF, which is reprinted in the *Zeit. f. Elektrochemie*,



July 24th. Briefly described, there is an alternator generating current at 110 volts and 100 periods, which is raised to 10,000 volts by transformers, and is used directly at this voltage to generate ozone. The apparatus itself consists of a large number of metal tubes, in each of which the ozone is formed by means of the so-called dark discharge, there being a special device (not described) which prevents any other and undesirable forms of discharge, such as sparks or arcs, and it thus becomes possible to work without any solid dielectric, which is a great advantage in practice, as glass would be the only dielectric to use, and this is apt to break. The air is first dried by means of chloride of calcium, and is then passed through the apparatus at the rate of 40 liters per minute or even faster. No cooling is resorted to and a concentration of 3.5 to 5 milligrams per liter is obtained, depending upon the speed of the air; from 3 to 3.5 has been found sufficient for sterilization purposes. This ozonized air is then pumped into the sterilizer, entering at the bottom and leaving at the top, as shown in the adjoining illustration, the coarse impurities in

the water having first been filtered off by means of a rapid filter. The article gives some details of tests which were made. The results are said to be at least as good as with other ozonizing systems, the figures for which are given in a small comparative table. The cost is said to be 1-16 to $\frac{1}{8}$ cent per cubic meter, by which he presumably means that much water and not that much ozonized air; this, though it may be a low price for ozonizing, is, nevertheless, rather a high price for sterilizing water. The cost of the installation, which presumably is not included in this, is not given, as it is said to depend on local conditions. The author of the paper fully agrees with the statement recently made by Ohlmueller and Prell, of the Imperial Board of Health, that a considerable destruction of micro-organisms is accomplished by ozonizing, and that in this respect it is generally superior to sand filtration. It is proposed to introduce ozonization at the water works in Rotterdam and, if this is done, the results will be awaited with great interest, although the prospects of reducing the expense, which seems to be the great drawback, does not seem to be very promising.

*Calcium Carbide.*—Now that the production of calcium carbide has grown to such enormous proportions, a discussion of the detailed reactions which occur during its formation become of interest. An article in the *Zeit. f. Electrochemie*, July 19th, by Gin, whose name is so well known in connection with this industry, describes these reactions in some detail. Strange as it may at first seem, it is known that the gases formed in different parts of the furnaces contain both free oxygen and free calcium; the former increases with the current density and is formed where the temperature is highest, while the calcium vapors issue from the places where the temperature is lower. The oxygen burns the electrodes immediately below the surface of the molten mass. The calcium is deposited in the form of a fine dust, which consists almost entirely of this material. To explain the formation of the latter he recalls some experiments of Berthelot, which showed that carbonous oxide is dissociated at high temperatures; there is also a surplus of calcium oxide in the charging mixture used, which is not always mixed according to the formula of Bullier. Moreover, there is always a series of layers in the mass in the furnace, the temperatures of which decrease towards the outside and in which, therefore, there are different chemical reactions, of which the more endothermic are at the higher temperatures. When the temperature is high enough to dissociate carbonous oxide entirely, the formation of calcium carbide consists of a simple substitution of oxygen by carbon in the calcium oxide, oxygen being set free, while calcium vapors are developed at the surfaces where the calcium oxide and the calcium carbide meet.—The present conditions of the calcium carbide and acetylene industries are summarized in an article by Muensterberg in *Rev. Gen. des Sc.*, June 15th. He goes so far as to say that the light of the future in small cities and in isolated buildings will be generated by acetylene, a statement which has been made before, but has not yet come true. Nevertheless, it is known that vast quantities of calcium carbide are now being made, and as they do not seem to be consumed in the large cities, they must go largely to the smaller ones.

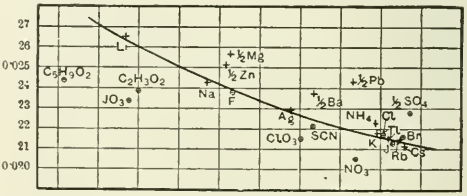
*Gold.*—Now that the unfortunate war in the Transvaal is at last over, attention is again diverted to the enormous gold-mining industry in that country. The general conditions of gold mining in the Transvaal, where the Siemens & Halske process is used largely, is discussed in an illustrated article in *Cassier's Mag.*, for July, by Hammond. While the percentage of extraction is said to be the same as in the zinc-precipitation process, the cost of the electrolytic process is said to be slightly greater, but the process may be supplied to any solution, whether weak or strong. As is well known, lead cathodes are used there, which are afterwards melted and cupelled, yielding a bullion of 0.880 in gold and 0.1 in silver; they are said to be removed once a month, which seems rather a long time as the daily interest on the value of the gold in such processes is often quite great. There is an installation, for instance, which the present writer has had occasion to examine, in which the stoppage of the plant for a single day involved a loss of interest amounting to several thousand dollars; this, however, was a refining process in which, of course, the amount of gold handled per day was far greater. It would seem that there was room for improvement in the use of a different kind of cathode, from which the gold could be stripped more frequently without involving the process of cupellation. The voltage used in this Siemens & Halske process is between 2 and 3, and the current density about 0.06 ampère per square foot of cathode.

*Tin from Scrap.*—The recovery of the tin from the waste scrap of tinned iron has occupied the attention of many inventors, but notwithstanding this, vast amounts of this material are being thrown away or merely melted for a low grade of iron, in which strength and purity are no object. A noted English writer once said that the greatest difficulty in the electrolytic process was not to get the tin from the iron, but to get the scrap itself. Although this may be the case, yet we believe that if a good commercial process is found the scrap will also be found, as is already the case in Germany. A process which seems to solve the difficulties was recently described in a very long article by Menicke in the *Zeit. f. Elektrochemie*, May 22d, June 5th and 12th. The scrap is used as an anode in a sodium hydrate solution, from which the pure tin is deposited on the cathode, while the iron and other impurities remain in the sludge under the anode. The formulas of the reactions are given, and he discusses at great length the practical questions involved. This process is in use on a very large scale in many large German cities, especially in Essen, and is claimed to be very remunerative, and to be one of the important electrochemical industries in that country. The price of tin is so high that it would seem that such processes could also be introduced to advantage in this country.

*Furnaces.*—A new form of resistance furnace for laboratory purposes, in which a spiral of platinum foil is used, is described in an article by Heraeus, abstracted in the Lond. *Elec.*, July 18th. Some formulas for determining approximately the temperature and efficiency of electric resistance furnaces is given in an article by Gin in the *Electrochem. Zeit.* for May.

## THEORETICAL AND EXPERIMENTAL.

*Electrochemical Theories.*—The modern dissociation theory, although a very valuable one and a very creditable one to its authors, has been so seriously attacked that it should still be, strictly speaking, called a hypothesis or, at least, limited to a narrower scope than its originators claimed for it. But as all such hypothesis when they have stood the test of trial sufficiently well to be applicable in practice are of great inter-



Mobility of ions and temperature coefficient.

est and value, articles on these theories, especially by such distinguished pioneers as Dr. Kohlrausch, the well-known president of the Reichsanstalt, and Dr. Hittorf, will always be read with interest. In one by the former, published in the *Sitzungsbr. Berl. Akad.*, May 29th, and abstracted in the Lond. *Elec.*, August 1st, he describes an interesting investigation, in which he succeeded in discovering and confirming a new law concerning the mobility and temperature coefficient of the

conductivity of monovalent ions. He seems to have found the interesting fact that the temperature coefficient is simply a function of the mobility, whatever be the chemical nature of the ion. Referring to the adjoining figure, the mobilities at 18° are shown as abscissas and the corresponding temperature coefficients as ordinates, and it will be seen from this that the monovalent ions Li, Na, F, Ag, K, Cl, Tl, I, Br, Rb, Cs, are all on the same curve, while ions of other valencies are not. Moreover, he found that the mobilities of the positive and the negative ions tend to become equal at rising temperatures. In attempting to frame a theory of this curious disappearance of the intrinsic differences of the ions, he conceives the ions as being surrounded with a film of water, whose thickness varies with the nature of the ion and reduces the mobility to a function of the friction of water against water, thus forming a third element which governs the two quantities, which he has shown to be dependent on each other. In the other paper above referred to, by HITTORF, the author shows his true scientific spirit by calling attention to, and correcting, a mistake in his determinations of transport numbers which he made about forty-five years ago. When clay diaphragms are used, there is no change of composition of the solution as it passes through the diaphragm, and in such cases there is no error in the transport numbers due to the diaphragm through which endosmosis always takes place; but when such diaphragms are made of animal membranes the action is different, at least for most aqueous solutions, as changes occur in the anode and cathode compartments which are not due to the electrolytic transference of the ions, even when the concentration is the same at the start, and, therefore, a determination of the transport numbers from the observed concentration changes may give wrong results. This is described in a Bunsen Society paper, in the discussion of which Le Blanc suggested that a diaphragm might be considered as a new kind of a solvent, in which the mobilities of the ions are different from what they would be in pure water, but the author did not seem to accept this hypothesis. The paper is reprinted in the *Zeit. f. Elektrochemie*, July 24th.

There is another paper on the theory of electrolysis, which was begun in the *Elek. Zeit.*, June, by PLATNER. It is a mathematical article on the electromagnetic theory of Maxwell and its application to the phenomena in electrolysis.

*Faraday's Law.*—It is a fortunate thing for electrochemists that Faraday's law, like Ohm's law, has so far withstood all attempts to show that it is incorrect, but, again like with Ohm's law, its application should be limited, or, in other words, it should be applied only to cases in which no other elements enter which are not really included in the law itself. Ohm's law, for instance, does not apply directly when counter e. m. f's. or reactances exist in the circuit; there are similar cases in the application of Faraday's law. In a recent paper by BOSE, abstracted in the Lond. *Elec.*, June 13th, he discusses the range of validity of Faraday's law, calling attention to disturbing factors. For instance, the cation may be capable of existing with two different valencies, and in such cases it might be claimed that the law does not apply; such a case, for instance, is the one in which one bivalent ion reacts with one atom giving two monovalent ions. In another case, to which he calls attention, the apparent discrepancy is due to secondary reactions, as, for instance in the deviations found in the electrolysis of silver salts, such as in the silver voltameter, which amount to 0.0001 of the total weight of the silver deposited; among the important secondary reactions is the occlusion of oxygen by the platinum electrode. It might be said that such cases are somewhat analogous to an unknown leakage in an electric circuit, in which Ohm's law could no longer be applied directly; such errors, however, are due to an incorrect application of the law and not to an incorrectness of the law itself. He regards Faraday's law as an absolutely exact law of nature, and believes that there is absolutely no evidence of any metallic conduction in electrolytes, the whole current being conducted by the transportation of materials. He compares Faraday's law with Dalton's law of multiple proportions, as far as exactness is concerned, and considers it an extension of Dalton's atomic laws.

*Heat of Combination.*—The probable source or origin of the heat of chemical combination is a fruitful source of speculation, and while probably of no great importance is, however, of considerable interest. T. W. RICHARDS, in a recent paper, calls attention to the fact that in many cases the contractions which are found to take place during different chemical combinations, are approximately proportional to the heat evolved, and he, therefore, believes that the whole source of chemical combination is the work performed in compressing the material; he carries this still further back and attempts to explain the origin of the heat of absorption, change of allotropic form and adhesion, which leads him to a hypothesis of the compressibility of atoms, which is discussed in detail. The paper is to be found in the *Proc. Am. Acad.*, Vol. 37, page 399, or in the *Zeit. Phys. Chem.*, Vol. 40, page 897, and is abstracted briefly in the *Am. Jour. Sc.* for July.

*Atomic Weights.*—While the question of atomic weights is a purely chemical one, yet the actual values are of such importance to electrochemists that laws concerning their relations are of interest here. Numerous papers have been written showing curious relations between atomic weights, intending to lead to some law existing between them, but most, if not all, of these fail to apply to some of the other elements. VINCENT, in a recent paper in the *Phil. Mag.*, for July, abstracted in the Lond. *Elec.*, July 11th, brings out a new numerical relation of this kind. He shows that the atomic weights are a certain power, namely, the 1.21 of a specific number for each element, which numbers are an ascending series and are always whole numbers, hydrogen being, of course, 1. This series shows certain gaps which he believes belong to elements which are yet to be discovered. A question, of course, is which serial number should be assigned to the element; iodine, for instance, shows the largest error, as the atomic weight thus calculated is incorrect by about 3.9 units, and to make this error fit his theory, he suggests that perhaps the wrong serial number was given to it; as these are all whole numbers, however, it would seem that there ought to be no difficulty in either finding the proper serial number, if the theory is correct, or if this cannot be found, then so much the worse for the theory. By changing its place with telurium, the results would correspond better with his law.

*Gaseous Electrolytes.*—Gases are found to have a property of being able to dissolve and ionize salts according to experiments made by HAGENBACH, described in the *Ann. d. Phys.*, No. 7, an abstract of which appears in the Lond. *Elec.*, July 4th. In his experiments he made a cell with platinum and copper electrodes, the solution being rubidium iodide in liquid sulphurous anhydride; rubidium iodide was chosen because it dissolved easily and had good conductivity. The resistance of the cell at 157° C., which is above the critical temperature, was 500,000 ohms, but the e. m. f. was not sensibly affected by this rise of temperature; it was 0.12 volt at 100° and 0.07 at 20°, while at the above-mentioned temperature it was 0.1. Iodide of copper was formed by the oxidation of the copper electrodes. He explains the low conductivity of gaseous electrodes by stating that while the gas is capable of ionizing a salt in solution, yet there are so many more chances for the re-combination in a gas than in a liquid that the number of free ions is kept very small.

*Sulphur.*—Among the other experimental researches described during the past month, is an article of some interest by RIEDER, published in the *Zeit. f. Elektrochemie*, June 5th. He found that a compound of copper and sulphur was formed electrolytically, or, at least, during an electrolytic process, under certain conditions. The cathode in the copper plating bath was made in the form of a bar surrounded by a non conducting cylinder of sulphur, but the bar was also exposed to the elec-

trolyte above this ring of sulphur, and after about twenty hours the sulphur cylinder had become blue black over its surface where it was in contact with the copper, while the latter had been eaten away somewhat at the same point. He believes that this compound acts like an electrolyte and that its formation continues deeper into the sulphur; if the latter is made conducting by the admixture of a powdered conductor, this compound forms all over the surface at once. He also tried using this compound as one plate of a battery, the other of which was zinc and the electrolyte ammonium chloride mixed with zinc chloride; when giving current, hydrosulphurous acid is formed, which in turn forms zinc sulphide; he does not, however, make any great claims for this combination as a useful battery. Another experimental research in which sulphur plays a part, was described by Kuester in a Bunsen Society paper, abstracted in the same journal July 24th. In electrolyzing polysulphide solutions, he noticed that the measuring instruments showed periodic variations, and upon investigation he found that they were due to a layer of sulphur on the anode, which was periodically formed and destroyed, acting like an insulator while it was there. He is still seeking for an explanation of the cause, but gives some preliminary results for the potential difference between platinum and silver electrodes and different concentrations of different chlorides saturated with sulphur.

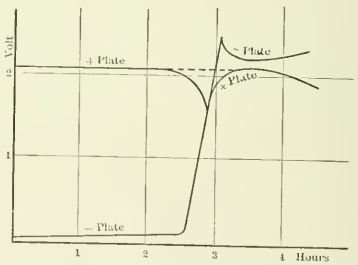
*Bromine.*—Kellner, several years ago, found that pure, dry chlorine gas had properties which ordinary chlorine has not, when high-tension currents are sent through it. In a recent Bunsen Society paper, published in the *Zeit. f. Elektrochemie*, July 24th, he describes experiments made with carefully-purified bromine in vessels of glass free from lead, and found that after some days yellow crystals had been deposited on the walls of the vessel, which he is sure do not come from the glass, but he does not know what they are. Some of those who discussed the paper concluded that it was a compound of bromine with the glass, while Ostwald suggested that it might be a case of isomerism.

*Alternating Current Electrolysis.*—This subject has been the basis of much research but as yet without much practical value, though nevertheless of interest. One of the ruling factors seems to be the current density, and we presume that the frequency of the alternations also has a considerable effect on the result, for it is not unreasonable to suppose that when the electrolytic process is not reversible a compound will be formed if the current continues in one direction long enough to overcome what polarization there may have been, and if the process is not reversible this compound will not change on the reversal of the current. Trotter recently made some experiments with alternating currents between lead plates, from which he concludes that such currents will electrolyze lead pipes if the current densities are lower than 1 ampère per square inch, which is an extremely high-current density, but the amount of the electrolysis, he claims, should be determined by those who advocate electric traction by alternating currents as a solution of the problem of destruction by return earth currents; but unfortunately those are the very ones who would prefer to assume that the amount was zero. The experiments are described in the Lond. *Elec.*, July 11th. He used lead pipes a few inches apart, separated by moist earth; the frequency was 83, the voltage 100 and the dampness was adjusted to maintain 1 ampère, which does not convey any idea as to the actual amount of dampness. He thus found that after six weeks there was a well-defined incrustation on the lead, confined to certain parts of the pipe. He repeated these experiments for other current densities. The nature of the earth used is also somewhat indefinitely described, as he stated he took it from his garden in front of the office.

*Chlorides.*—Mueller, in the *Zeit. f. Elektrochemie*, July 3d, gives an illustrated account of experiments in which he investigated the electromotive behavior of hypochlorus acid and chloric acid, in which he found a great difference when he used plain platinum anodes and when he platinized them, obtaining much better results in the latter case.

## PRIMARY AND SECONDARY BATTERIES.

*Lead Batteries.*—Several articles have been published recently on the lead accumulator, some of which are of interest as showing that although this is a well-threshed-out subject, there are still matters of interest cropping out. Frequently the plates of an accumulator are simply connected together regardless of their individual capacities, and then as a rule the useful capacity of the whole accumulator depends largely upon the weakest plates, especially with high discharges. It is therefore of interest to be able to determine the behavior of individual plates, or groups of plates, during a discharge, as in a well-constructed accumulator, where lightness is an important consideration, it is very desirable to have all the plates of exactly the same capacity and the end plates of half the capacity of the others. This may be done by means of an auxiliary electrode which serves to measure the potential difference between that electrode which is assumed to be standard and the plate to be tested. A method known as Fuch's method was recently applied by Liebenow, whose name is well known in connection with accumulator researches, and is described by him in a recent Bunsen Society paper which has not yet been published in full, but is abstracted in the *Elek. Zeit.*, June 12th. He applied it to a battery with two



DISCHARGE CURVES.

plates, or sets of plates, and claims that the method is very useful in repairing batteries that have lost their capacity. He describes three different forms of auxiliary electrode. The first consists of a cadmium plate in an ebonite frame, and is sufficiently good for rough determinations; care should, however, be taken that when the plate has been used the sulphuric acid should not be left to dry on it, as cadmium sulphate would be formed, which would cause errors in the next test. Zinc instead of cadmium is not suitable because zinc dissolves much more rapidly in sulphuric acid than cadmium. For more exact measurements Liebenow uses solid cadmium amalgam, which is suspended in a small bottle of "Pukall" material (a material much used in Europe for porous diaphragms) and is surrounded by a solution of cadmium sulphate and sulphuric acid; such an electrode is very constant. It is placed over the plates in the accumulator. During the discharge of the e. m. f. between this auxiliary electrode and the two battery electrodes is measured and the curves are plotted with the e. m. f's as ordinates and the times as abscissas. A sharp bend in a curve shows that the capacity of the plate is exhausted. For very exact measurements a small, carefully-treated accumulator plate is suitable; as an auxiliary for testing the negative plate a small, spongy, lead plate is used, and for testing the positive plate a peroxide plate may be used, as very sensitive voltmeters can then be used on account of the smallness of the e. m. f's. There are cases in which both curves show sharp bends, although only one plate is exhausted. The adjoining diagram has been plotted from tests of a

storage battery the negative electrode of which had a smaller capacity than the positive one. At the beginning of the discharge the negative plate has an e. m. f. of 0.1 volt against cadmium; this e. m. f. increases slowly until the plate has been converted into sulphate; after two and one half hours the e. m. f. increases rapidly to about 2.5 to 2.6 volts, when the "discharge" is continued by force, by continuing to send a current through the cell; the negative plate then becomes peroxidized. The curve has a sharp maximum when a strong development of oxygen occurs; it then drops, the development of oxygen stops, and the curve takes the shape of the normal one of the peroxide plate. On the other hand, the positive plate has, at the beginning of the discharge, an e. m. f. of 2.1 volts against cadmium, and the curve drops definitely when the plate is discharged; this normal behavior is represented first by the full line, then by the dotted line and finally by the full line. In certain cases, however, the curve drops before the capacity of the plate is really exhausted; in such cases it occurs at the same time when the curve of the other plate shows a sharp bent; but the curve of the positive plate rises again after it has met the other curve (*i. e.*, from the point where the e. m. f. of the battery is zero); it drops later again definitely when the plate is really exhausted. This behavior is represented in the adjoining diagram by the full line throughout. It looks as if the curves for the two plates influence each other. In such cases the Fuch's method gives wrong results, as it seems to indicate that the positive plate is exhausted at the front bent of its curve, which is not really the case. Only by continuing the experiment, as is done in the adjoining diagram, the real condition would become evident, but it is, of course, impossible in practice to do this. He explains this peculiar phenomenon as follows: If at the ends of a battery there are plates of the same capacity as the plates in the center, then the end plates are not yet exhausted when the plates in the center are; the lines of current then no longer go from plate to plate, but around the sides of the plates in the center, that is, there are "stray" currents; the same is the case when the contacts of a plate are bad and when it is not discharged uniformly with the other plates; such stray currents cause wrong measurements.

Although the Faure type of accumulator was considered at the time of its first invention to be a very great improvement over the older Planté type, yet experience covering many years has shown that this view was premature, as for the positive plates at least, many makers, have gone back to the Planté type. The objection to this is, of course, the cost of formation. While it may almost be assumed that most chemicals had already been tried for hastening this formation, yet PETERS with the proverbial patience of a German, has, it seems, spent an enormous amount of time and patience making an almost endless number of experiments with a very large number of chemicals, and with the thoroughness of his countrymen he seems to have made these experiments systematically and intelligently, and gives the results so that they have a real value. For a long time past he has been publishing the results in the *Centralbl. f. Accum.*, and while they have not yet been completed, they are of considerable value as they indicate that quite a number of materials will give fairly good results, while others give practically nothing. It would be impossible to give all the results here, and readers are referred to that excellent journal for the figures; a few of them, however, published in the numbers of April 1, May 1, and June 1, may be repeated here. Theoretically, 100 ampere hours could form 222 grams of peroxide of lead; the results given below were obtained with a current of 0.6 ampère and a surface of 144 sq. cm. About 35 grams of peroxide were obtained from 900 c. c. of a 15 per cent. solution of magnesium sulphate mixed with a solution of 30 grams of ammonium sulphate and 20 grams of crystallized hydroxide in 100 c. c. of water; 3.5 were formed in 30 grams of crystallized magnesium sulphate and 20 grams of sodium sulphate free from water added to 1 liter of water, the specific gravity of the solution being 1.020; about 1.10 grams, in a solution of 30 grams of bichromate of potassium and 12 c. c. concentrated sulphuric acid in 1 liter of water. The other results given in those parts are below these, but in other portions of his series of articles he gives results far superior to those given in these later parts. It may be assumed that after working as hard as he has he will not publish to the world the best results, and in this connection a small advertisement in that journal is of interest, as it states that a process for the formation is for sale, but does not state that it is his process.

The same journal of June 15, contains an account of a long series of tests made of French storage batteries to be used in the French navy. They were all discharged together in series, the discharge being stopped when the e. m. f. had fallen to 1.65 volts, and when this happened in less than half an hour the cell was not considered. After 251 discharges there were still five batteries left, four of which had pasted plates throughout, while the fifth had formed positive plates and negative pasted plates. There were altogether at the start 21 batteries by 13 different makers, 11 of which had pasted plates throughout, nine had formed positives and pasted negatives, while in one both plates were formed.

WEHRLIN AND LANGSTEIN, in the *Centralbl. f. Accum.*, June 15th and July 1st, have an article on troubles with storage batteries, in which they discuss these and give various reasons for the gradual destruction of the plates.—At the recent DUSSELDORF EXHIBITION a number of storage batteries were exhibited, some of which are described in that same journal, May 15th and July 15th.

*Other Forms of Storage Batteries.*—The lead-zinc storage battery has tempted many inventors, and descriptions of it crop out periodically, but in every case, as far as we can recall, it again vanishes as a failure; it seems to survive only as a sort of temporary storage device for very short periods, such as when used as an equalizer for brief periods of fluctuations. We fear there is little hope of this type of cell coming into practical use, but its great capacity per pound still makes it a very tempting direction for possible improvement. GABRAN, in the *Elek. Zeit.*, June 26th, describes some experiments with such a battery, accompanied by diagrams and tables. The case is made of copper, amalgamated on the inside and divided into departments by means of perforated amalgamated sheets, all of which form the negative plate, while the positives are ordinary peroxide plates, the electrolyte being, as usual, zinc sulphate and sulphuric acid. The cover and all binding posts are made of aluminum, which we fear is not a wise departure. Discharging it from 2.4 to 2.1 volts during a period of ten hours, he obtained with one battery 331 watthours for 14.3 kg. of total weight, and with three others 50.6, 81 and 72 watt hours, respectively, for 3 kg., 2.5 kg. and 2.5 kg. of electrodes alone. He experimented with them for a year and a half and finds no reason why they should not be used in practice; he claims that the copper is not attacked. While it may be true that the copper was not attacked in his cells, it is hardly likely that this would be true when the cells are used in practice, for if a single cell in a series should be overdischarged, the copper is sure to go after the zinc, which has been deposited on it during the charge, is all gone. There is another serious objection to this type of cell, which is not generally stated and perhaps not generally known. It is that the sulphuric acid is electrolyzed easier than the sulphate of zinc during the charge, which means that much of the charging current will be used to generate hydrogen on the cathodes, and this is especially the case when the contents of the zinc sulphate in the solution gets low towards the end of the charge. It is for this reason that it is almost impossible to get zinc out of a zinc sulphate solution when there is present a large amount of sulphuric acid; this wasted current will also evolve oxygen on the peroxide plates, as they will of necessity be fully charged long before the corresponding amount of zinc

has been deposited on the cathodes. We fear that this battery is a theoretically hopeless case, unless some solvent for zinc can be found which is equally effective in generating a high e. m. f., and which will decompose at a higher voltage than the zinc solution.

The *Centralbl. f. Accum.*, July 15th, contains an abstract of a patent of GAHL, who proposes to make porous silver oxide electrodes, like those used in the Jungner cell, in alkali storage batteries. He mixes fused-silver chloride with about 15 per cent. to 20 per cent. of lead chloride, and then removes the chlorine by using the plate as a cathode in an alkaline-hydrate solution; then removing the lead by using the plate as an anode in another solution, which is not given, the silver being at the same time oxydized.

*Standard Cells.* The very exhaustive series of tests of the Clark and the Weston cells, conducted more especially at the Reichsanstalt, have greatly increased the confidence which one can now have in their constancy and reliability. In fact, they are now, together with the standard resistances, the real basis of exact electrical measurements; they can now be made to be exact and uniform to within 0.01 per cent. and will remain constant within this limit. Among the recent papers on such cells is another emanating indirectly from the Reichsanstalt, by JAEGER, who has devoted much time at that institution to a study of these cells; it is a Bunsen Society paper, published in the *Zeit. f. Elektrochemie*, July 24th, and abstracted in the *Centralbl. f. Accum.*, July 15th. He first discusses at some length the Clark cell with saturated electrolyte, and an excess of solid zinc sulphate, several forms of which he describes and illustrates. At 15° C. the generally accepted mean value of the e. m. f. is 1.433 volts, which is in exact agreement with Carhart and Guthe's determination. The formula accepted by the Reichsanstalt for the e. m. f. $E$, in international volts at the temperature $t$ degrees C., is $E = 1.4328 - 0.00119\ (t-15) - 0.000007\ (t-15)^2$. He briefly discusses the changes taking place in the Clark cell at a temperature of 30°, which are interesting from a physicochemical point of view. As the high temperature coefficient of the e. m. f., which is about 0.08 per cent. per degree, necessitates a troublesome correction, Weston and Carhart have proposed using a dilute zinc sulphate solution; for instance, saturated at 0° C., in the temperature coefficient is thereby diminished to one-half, but such cells have not been defined with sufficient precision. He then mentions briefly the Helmholtz calomel cell, consisting of zinc, zinc chloride, calomel and mercury, but it is not suitable as a standard cell, because different cells do not give uniform values; the calomel does not seem to be a sufficiently good depolarizer. The Weston cadmium cell is an excellent standard cell and has a very small temperature coefficient; he believes that in course of time it will entirely replace the Clark cell. The Weston Co. use a dilute solution of cadmium sulphate, saturated at 4°, while the measurements made in the Reichsanstalt were nearly always made with a saturated solution, with an excess of solid crystals. For a cell with dilute solution the temperature coefficient is practically equal to zero within the ordinary temperatures; the e. m. f. is 1.0191 international volts. The e. m. f. $E$, in international volts of the cell with saturated solution and crystals, is given by the formula $E = 1.0186 - 0.000038\ (t-20) - 0.00000065\ (t-20)^2$. At 4° C. both types of cells have nearly the same e. m. f.; neither shows a lagging of the e. m. f. behind the temperature, a fact which is self-evident for cells without crystals; there is no cracking of the vessel at the negative pole on account of the amalgamation of the platinum wire and there is no development of hydrogen. The cadmium amalgam must have between 5 and 14 per cent. of cadmium. Contrary to some experiments by others, the very numerous measurements of the Reichsanstalt have not shown any irregular behavior whatever of the Weston cells at 15°, provided a cadmium amalgam below 14 per cent. was used. From measurements extending over several years, the following values of the ratio of the e. m. f's. of the Clark and the Weston cell were found: Clark at 0° to Weston at 20° 1.42280; Clark at 15° to Weston at 20° 1.40669. These ratios have not changed by more than 0.0001 in four years. A standard cell must represent a reversible chemical system and would theoretically have the best form, if the electrolyte is also present in solid form. The depolarizer is best when solid and a good conductor. When mercurous sulphate is used, there are complications due to its solubility.

There was another article, also a Bunsen Society paper, in the *Zeit. f. Elektrochemie*, July 24th, by LUTHER, in which he discusses the question of the degree of chemical purity of the electrolyte in order to obtain the required exactness. He considers a Clark cell with saturated zinc sulphate solutions and zinc sulphate crystals, and investigates, by a thermodynamical several years, the following values of the ratio of the e. m. f's. be when the zinc sulphate solution contains an addition, say, of glycerine. He imagines two Clark cells connected against each other; that is, positive connected with positive, the electrolyte of the one being pure and that of the other containing glycerine. This system is imagined to first give out current and then to be brought back again to its initial condition by means of isothermic distillation. From the laws of thermodynamics, it then follows that the e. m. f. of this system, namely, the difference between the e. m. f's. of the two cells, depends only upon the ratio of the vapor pressures of water of the electrolytes of the two cells, a conclusion which he then confirmed experimentally. One Clark cell contained an impurity of 50 per cent. by volume of glycerine, while the electrolyte in the other was pure; the difference of the e. m. f's. of the two cells was found to be 0.00744 volt at 25°, from which he obtains, by means of his theory, the ratio 1 to 1.09 for the vapor pressures, while it was found experimentally to be 1 to 1.10, thus confirming his theory. He draws the following interesting conclusions from his theory: if the solid crystals in a standard cell with saturated solution (corresponding to the zinc sulphate crystals in a Clark cell with saturated zinc sulphate solution) are free from water of crystallization, then the e. m. f. must be independent of impurities and of the solvent. He is trying to devise a practical standard cell in which this condition is fulfilled.

## GENERAL AND MISCELLANEOUS.

*Silver Voltameter.*—The sources of error in the silver voltameter were the subject of careful research by the Reichsanstalt some years ago, and it was then shown that for precise measurements very great care must be taken, as the sources of errors are quite serious, so much so that it really becomes quite difficult to use it, and the standard cell, combined with the standard ohm, therefore gives a more reliable ampère. LEDUC has recently presented a paper to the French Academy, published in *Comptes Rendus*, July 7th; *L'Eclair. Elec.*, July 26th; *L'Ind. Elec.*, July 25th, and Lond. *Elec.*, August 1st, in which he discusses some of these sources of error. One lies in the change produced in the acidity or alkalinity of the solution, some observers claiming that it becomes acid, while others say it becomes alkaline; this, he shows, is entirely a question of circumstances, such as the rapidity of the electrolysis. The nitric acid which is generated is electrolyzed at the same time as the nitrate of silver itself, but no hydrogen is evolved, as it precipitates silver from the nitrate and also forms a complex compound with nitrogen and hydrogen. There is popular misapprehension that the deposit of silver on the cathode is corroded by the solution, but he shows, by careful weighings, that such a corrosion does not exist. On the other hand, there must be an appreciable polarization of the cell, which is usually supposed to be negligible; he estimates it to be 0.03 volts. He mentions the fact that if a silver plate is put into the cell, but not connected to the circuit, it shows a slight loss of mass, whereas there is no such loss when a silver needle is used instead; the loss in the case of the plate depends upon the way in which it is immersed, being greater when it crosses the current.

## CORRESPONDENCE.

### THE PROSPECTS OF THE ELECTROCHEMICAL INDUSTRIES.

*To the Editor of the Electrochemical Industry:*

SIR: The year 1902 will mark an epoch in the development of practical electrochemistry in the United States. Heretofore, patient experiment, close thinking and hard work on the part of individuals have resulted in the commercial success of certain electrochemical establishments. All that has been done has been the result of unorganized effort and American "get-thereness." There have been some bad wrecks and on the shore are seen the hulks of once fair craft, stranded because of the lack of knowledge of previous failures. For "by our failures do we learn rather than by our successes."

At the present day, we see several of our universities and technical institutions offering courses designed to furnish their students special knowledge of electrochemistry. We also see the founding of a society which brings the practical men and the theoretical men together, and where also an enlightened self-interest has caused frank discussions of practical problems to be in order.

Finally, we witness the start of a technical journal with good auspices, which journal will chronicle the progress of this new applied science in its vigorous youth—at the same time helping the growth to be normal, yet rapid.

That such a field now exists is to my mind shown clearly by the low rates that hydraulically generated power can be bought at the present time. Such inducements are offered for electrochemical works to locate, and the terms are so attractive, that one is forced to the conclusion that these large plants will to expand and to sell power in large amounts at a small profit. The potential supply certainly exceeds the possible demand.

In any electrochemical process, be it electrolytic, electrothermal or a combination of the two ways, the cost of power is a large fraction, often 25 to 90 per cent. of the entire cost. The old electrochemical theory of Berzelius is so modified that we know that variations in chemical potential are strictly proportional to variations in electrochemical potential. For example, lead is easier reduced than zinc, zinc than magnesium, magnesium than sodium. In their electrolytic potential these metals stand in the same relative positions. Similar facts can be stated in regard to the non-metals, e.g. fluorine, chlorine, bromine and iodine.

Accordingly, it can be asserted that any metal can be reduced or any compound formed by using the corresponding potential. This is not strictly true, but in an approximate manner, because uniform conditions cannot be maintained. Easily studying the conditions of temperature, current, electrolyte, etc., it may be said that the majority of chemical products can be produced by electrochemical means. The electric furnace has also put at the disposal of the electrochemist or metallurgist such temperatures that many chemical changes can be effected. "Electrochemistry" is the name to be given to the resulting thermal potential.

Cheap power is, of course, the foundation stone on which the electrochemical Archimedes is to carry on commercial success in the manufacture of chemicals. Fuels, labor, discoveries of materials, convenience to markets, easy questions to be solved, will be settled as the great power plants become more and more the industrial centers. The United States has in these points a greater possibilities for development than any other country, because they are near at hand to our water-ways and not too far distant from present centers. The falls of Niagara are commercially in touch with New York. The falls of Zambesi are commercially remote from London. The law of inverse squares holds here in business as in gravitation.

The utilization of this power is the "electrochemical industry." The journal bearing that name must co-ordinate incubate ideas, simplify practice, extend our knowledge of the [illegible] We [illegible] from the Pierian [illegible] to the [illegible] achievement. The [illegible] of the ELECTROCHEMICAL INDUSTRY [illegible] to feel we believe that it will fill the long want.

Yours very truly,
WOOLSEY McA. JOHNSON.

New Brighton, N. Y.

## BOOK REVIEWS.

ELEMENTARY PRINCIPLES IN STATISTICAL MECHANICS. DEVELOPED WITH SPECIAL REFERENCE TO THE RATIONAL FOUNDATION OF THERMODYNAMICS. By J. Willard Gibbs. New York: Chas. Scribner's Sons, 1902. 207 pages. Price, $3.00.

This is one of the volumes of the "Yale Bicentennial Publications," issued in connection with the bicentennial anniversary of Yale University, "as a partial indication of the studies in which the University teachers are engaged," and Old Yale may be proud of J. Willard Gibbs.

Prof. Gibbs' studies in thermodynamics and in the application of thermodynamical methods to problems of physical chemistry, were begun many years ago. The work that Gibbs has done in this line in his younger years, was ahead of the time and, moreover, was of such a highly theoretical and analytical nature that it appealed to only very few, and was soon forgotten, until in the last ten or fifteen years the rapid and enormous development of physical chemistry in general and especially of electrochemistry set in. Attention was then directed to Gibbs' early work, especially by German scientists. Planck, in starting his valuable thermodynamical investigations, followed closely the footsteps of Gibbs, and Ostwald translated the early important papers of Gibbs into German. It soon became apparent that many interesting results obtained independently by new investigators had been anticipated many years ago by Gibbs. Since then Gibbs' name has become more popular, and as an indication that he is now well known even in his own country, we may recall the hearty applause that followed a few well chosen words spoken in his honor by Prof. Carhart in a discussion of a paper at the inaugural Philadelphia meeting of the American Electrochemical Society.

This latest book of Prof. Gibbs is of the same highly theoretical nature as his former work. To read the advanced student it is very difficult reading, as it requires a thorough knowledge of the higher mathematics and of mathematical physics. "Statistical mechanics" [illegible] a branch of mathematical physics which has [illegible] to explain the [illegible] and of which Clerk-Maxwell and Boltzmann are the [illegible] founder. Prof. Gibbs in the present book [illegible] statistical mechanics [illegible] to thermodynamics, [illegible] done in his former papers, but in such a way as to show in how ways [illegible] and thermodynamical principles [illegible] new light.

While the work is of the highest value from a theoretical point of view and will be appreciated by the advanced student, it can hardly be said to be practical in the ordinary sense of the word. It cannot be overestimated that the theory of electrochemistry of the future will be based on the principles of thermodynamics. But to make such a theory a practical tool for the consulting engineer, it will be necessary to find a rational foundation of thermodynamics itself. From the point of view, Prof. Gibbs is undoubtedly right to attempt to put such a foundation on statistical mechanics, but others look at this from a different standpoint. We are still far from having established thermodynamical terms and methods; to mention only one example we may quote James Swinburne's recent attempt to attack the problem from the electrical point of view; he is primarily an electrical engineer, so he tries to develop the principles of thermodynamics in a way strictly analogous to

the theory of electricity. From the point of view of an electrical engineer this is a "rational" starting point, but whether it will lead to a complete and correct demonstration of thermodynamics, it is for the future to show.

Prof. Gibbs' book is divided into 15 chapters. In the first he gives the general ideas and discusses the "principle of conservation of extension-in-phase." In the second and third chapters he applies this principle to the theory of errors and to the integration of the differential equations of motion. In the fourth and following chapters he considers statistical equilibrium and conservative systems. He treats especially of what he calls the "canonical" distribution, in which the index of probability is a linear function of the energy. While in other chapters he often touches briefly on thermodynamical analogies, the fourteenth chapter is devoted entirely to this. In the last chapter he deals with systems composed of molecules; he introduces this supposition at the end of the book, because he wants to separate very decidedly the purely thermodynamical laws from those special modifications which belong rather to the property of matter.

Transactions of the American Electrochemical Society. Vol. I. Philadelphia: Inaugural Meeting, 1902. Published by the Society in Philadelphia. Price, $3.00 in cloth; to colleges, libraries, societies and journals, $2.00; to members, free. 250 pages; illustrated.

This is the first volume of the transactions of this new national society, which was formed in Philadelphia last April at the suggestion of a few electrochemists in Philadelphia, who had been meeting informally for several years to discuss electrochemical subjects. A preliminary meeting of the more prominent electrochemists in this country was called in Philadelphia last November to discuss the question of founding such a society, and it was decided that if 75 members could be secured the society should be founded and a formal meeting arranged for. While some of those who attended the preliminary meeting, and a number of those who sent their opinions in writing, had grave doubts about the advisability of starting such a society, the majority were of a different opinion. The fact that in a short time about 350 members were secured, showed that the time was ripe for the formation of such a society.

The present volume consists chiefly of the 20 papers that were read at the first formal meeting. These are published in full and are followed by the revised stenographic report of the discussions, which latter are in a number of cases extremely interesting. A number of these papers are illustrated, some of them with half-tone inserts. It would require much space to give even a brief review here of the papers themselves; it suffices to say here that they included a wide range of subjects on industrial, theoretical and experimental work or subjects, and on instruction in electrochemistry, many of them are of considerable interest. With perhaps one unimportant exception, these papers are all new and original matter. The intention seems to be to publish a volume after each meeting, the number of meetings depending upon the number of papers which can be secured, and other considerations.

A somewhat peculiar and striking color has been chosen for the cover of these *Transactions*, evidently for the purpose of attracting attention, as we do not remember having seen any book or journal with a cover of the same color.

Besides the papers this volume contains a portrait of the first president, Joseph W. Richards, some introductory remarks by the president, a historical sketch of the formation of the society, the proceedings of the business meetings, the constitution, and the catalogue of the members; those in the present list have the honor of being called charter members. The general make-up of the book is about like that of the transactions of other national societies and is very creditable to such a young society. These transactions promise to become important in the literature on electrochemistry.

## REGULATING RHEOSTATS.

While rheostats are a necessary accessory in nearly all the different branches of electrical engineering, they are of special interest to electrochemical engineers for two reasons: first, because successful operation of electrochemical processes generally requires that the voltage and the current necessary for a special purpose are maintained with great exactness during the operation; second, because the use of relatively very high currents for electrochemical processes has made a special design of rheostats indispensable for such purposes.

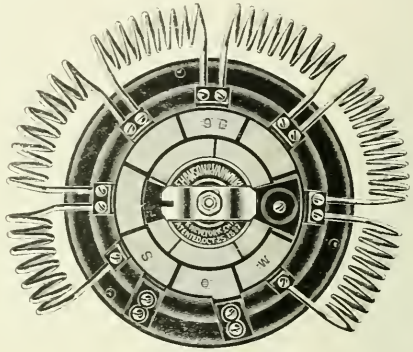


FIG. 1.—DYNAMO RHEOSTAT.

For instance, any electroplater knows that different voltages are required to operate successfully different kinds of solutions. If the correct conditions are not maintained during the process of electroplating, the results are unsatisfactory; if the current becomes too great (*i. e.*, if the e. m. f. applied at the terminals of a given electroplating tank is greater than required) there is a tendency to burn and blacken the work to a marked degree.

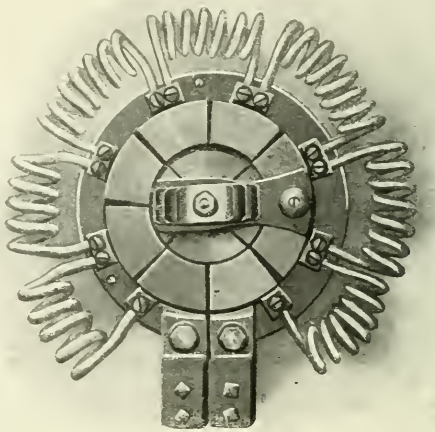

FIG. 2.—RHEOSTAT FOR ELECTROCHEMICAL PROCESSES.

The accompanying illustrations represent three rheostats made by the Hanson & Van Winkle Co., of Newark, N. J. The rheostat shown in Fig. 1 is made to carry from 10 to 250

amp. and is used for various purposes, especially in connection with dynamos; in the smaller sizes for field regulation and in the larger sizes for carrying the main current.

Figs. 2 and 3 show rheostats for use in electrochemical processes and especially in electroplating. The rheostat, Fig. 2, carries currents from 800 to 1,000 amp. without excessive heating; the duplex rheostat, Fig. 3, carries currents of 2,000 amp. It has sufficient wire to allow of toning down the highest electromotive force used in electroplating. Enough segments are used to reduce the e. m. f. to two volts and at the same time avoiding any excessive heat and danger from fire. All the segments, lever arms and connections are made of a special copper casting, and their calculations are all based on a carrying capacity of 1,000 amp. per square inch. These are mounted on an iron base, which is insulated from the copper segments with a specially prepared vulcabeston insulating material, heat or moisture having no effect upon it. The rheostats are then mounted on marbleized slate and the whole is then mounted on a handsomely polished oak base board. As there is always a great deal of moisture and acid fumes in a plating room, the resistance coils are given a heavy deposit of zinc, which amply protects them from rusting. These coils are made from a special resistance wire, which

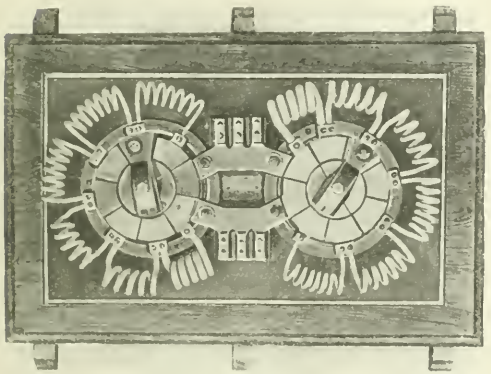

FIG. 3. MULTIPLE RHEOSTAT.

is carefully tested for its resistance and carrying capacity, and graduated on each rheostat from a light to a heavy wire according to the current it has to carry, and at the same time giving sufficient reduction in voltage for a large or small amount of work.

The multiple rheostat, Fig. 3, has the advantage that one of the resistances can be thrown out of the circuit by moving the lever arm on the off segment. This can be done when a current of 1,000 ampères or less is being used. By this method four times the resistance is obtained. As the load is increased the other rheostat is thrown in the circuit. This size of rheostat is used in the main line to control the voltage of several large tanks, or very large galvanizing and acid copper solutions, also for special purposes where large currents are to be used.

The Hanson & Van Winkle Co. have for many years installed numerous successful plants for electroplating. Their stock of apparatus and accessories, required for cold galvanizing plants, is complete. They also carry in stock chemicals, polishing lathes, polishers' and buffers' supplies, grinding machinery, plating dynamos and lacquers.

## EXTERNAL SHUNT AMMETER.

Special electric installations require special measuring instruments. The rapid and enormous development of high-tension power transmission in recent years has necessitated special devices and designs for instruments to be used at very high voltages. On the other hand, in electrochemical industries it is the current which is abnormally high; and, as for electrochemical processes, it is generally essential to keep the current strength under control. It is important to use ammeters, which enable an exact measurement of very large currents and which, at the same time, consume only a small amount of energy.

The accompanying illustration shows a Weston ammeter of the "external shunt" type, which involves a method of action quite different from that of the usual type of ammeter.

The difference of potential between two points on a conductor is directly proportional to the current passing through the conductor. If, therefore, the resistance between two points of a certain conductor is known and we want to measure the current which passes, a voltmeter connected at these points can be used to measure the current. Or if we know, in one case only, the potential difference which exists between the two points when a known current passes, then we can find in any case the current by measuring the potential difference. For example, if a voltmeter is connected to two points on a conductor, and it is known that with 1,000 amp. passing through the conductor the potential difference between these points is 0.01 volt, then a reading of 0.0155 volt on the voltmeter indicates that the current at that moment is 1,550 amp.

To make this method of measuring the current strength practical it is essential that the voltmeter used is sufficiently sensitive, so that a potential difference between the binding posts amounting to a small fraction of a volt will cause the pointer to move across the entire scale.

EXTERNAL SHUNT AMMETER.

It must be remembered that any drop of potential involves a loss of useful energy, and consequently there should not exist a great difference of potential between any points of a conductor on the same side of a translating device. The cross section of all conductors should be large enough to reduce this loss as much as is practical. The limit is reached when any increase in efficiency obtained by increased cross section of the conductor would be overbalanced by the increase of interest on the cost of the conductor.

The Weston shunt ammeter is, in fact, a voltmeter of high sensitiveness which gives a full scale deflection with 0.03 volt between its binding posts. In any plant such a small potential difference between points of the conductor will be found. In case the cross section of the conductor is based on one square inch copper per 1,000 amp., only a length of about 4½ feet would be required.

It will be seen that the conductors have not to be lengthened, bent or specially shaped in order to accommodate the ammeter, but that the instrument proper can be connected to two points of different potential by thin connecting wires. The maximum current flowing through the instrument never exceeds 0.06 ampères. Of course these connecting wires are an integral

...therefore, when ...not be altered.

...electrical plant consist...ance considerably with ...preferable not to use a part ...instrument, but to insert ...alloy having a small ...coefficient.

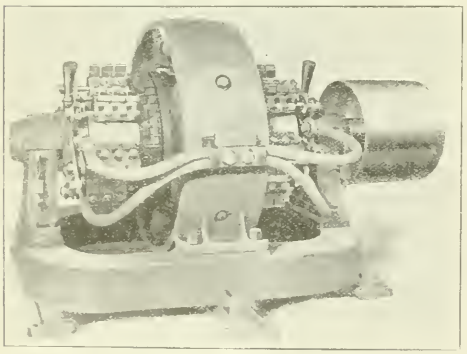
This has the further advantage that the combination of instrument and shunt can be properly adjusted in the laboratories of the manufacturer.

...expenditure for copper and labor required for installa... is reduced by shunting the instrument, and a decrease in ...expenses is effected by the extreme sensibility of the ...instruments. As already stated the Weston ammeter ...a potential difference of 0.03 volt between the binding ... takes 0.00 amp. for full scale deflection. It con...ture, not more than 0.018 watt, whereas, most, if ...meters of other types consume from 800 to 1,000 ... when measuring a current of 1,000 amp. Especially ...powerful currents are used, these savings often exceed ...total cost of the instrument.

The Weston Electrical Instrument Co., Waverly Park, N. J., manufacture these instruments in different styles of any required capacity, with and without illuminated scale, and also make voltmeters ranging from a fraction of one volt for full scale deflection up to 10,000 volts, and higher. Their line of portable testing instruments is complete and covers all special requirements met with in the different branches of electrical engineering.

## ELECTRO-PLATING DYNAMOS.

Twenty-one years ago, in a building on Market street, Hartford, Conn., Arthur E. Eddy began the manufacture of dynamos for electroplating, and from that time the name "Eddy" has been accepted by users of this class of apparatus as guaranteeing the quality both with regard to con...



...PLATING MACHINE.

...operation ...with all other forms of electrical ...machinery, the modern dynamo for electrolytic work is very different in design from the first ones, yet that they were good in every way is proved by the fact that several of the eleven first made are in commercial use to-day.

The maintenance of the enviable reputation of the "Eddy" machines is due to the fact that great care has been exercised in their design, the results of both theoretical and experimental researches being fully utilized.

The modern dynamo for electrolytic work must be simple, durable and efficient, maintaining its voltage, and running sparkless under charge of load without the necessity of shifting the brushes, and in the above particulars the "Eddy" machines are believed to be unsurpassed. Several years ago the use of the three-wire system in connection with machines of this class was found desirable, and double-commutator machines were designed. The saving in line loss and convenience of having two voltages available, more than com...

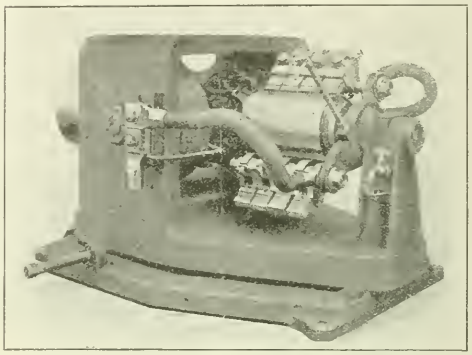


FIG. 2.—BIPOLAR ELECTROPLATING MACHINE.

pensates for the slightly increased initial cost. That low voltage, high-current machines without commutators could be made was also realized, and such a machine is in operation to-day, but the output in current and the necessary weight were so great that very little demand for them was to be expected. The accompanying illustrations show some of the machines as above described.

Fig. 1 shows the double-commutator, six-pole type, each

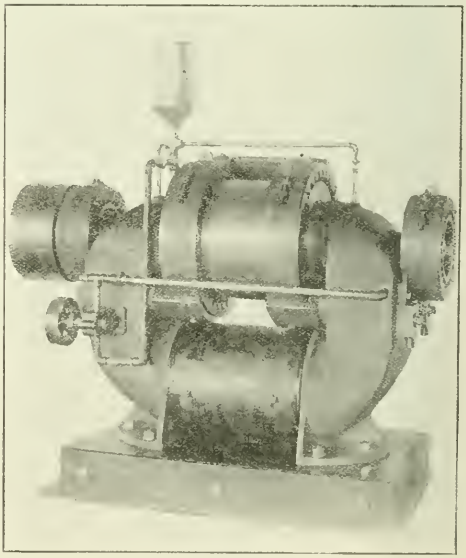

FIG. 3.—UNIPOLAR ELECTROPLATING MACHINE.

armature winding being independent, and the machine so made that they may be connected in series or parallel, giving either the sum of their voltages with the current of one, or the voltage of one and the current of both. Five or more volts per commutator is the ordinary practice, depending upon con...

dynamos. Seven and one-half, 10 and 30 K. W. machines have been made of this type.

Fig. 2 shows the latest two-pole type, of which 5, 20 and 75 K. W. machines have been made.

Fig. 3 shows a unipolar or continuous-pole machine, designed for 2 volts and 6,000 amperes, and [illegible] when tested 9,000 amperes.

Eddy machines for electrolytic work have been made up to a capacity of 150 K. W., and will be made in future by the Eddy Mfg. Corporation, Windsor, Conn.

## PERSONAL.

PROF. F. HABER, of the Institute of Technology, of Karlsruhe, Germany, and Prof. R. S. Hutton of Owens College, Manchester, England, are visiting this country to study the development of the electrochemical industries in the United States. Both gentlemen will attend the meeting of the American Electrochemical Society, at Niagara. Prof. Haber is the official delegate of the German Bunsen Society (which is the German branch of the German Electrochemical Society). Prof. Haber is the author of an excellent German treatise on industrial electrochemistry from a theoretical basis.

## INDUSTRIAL NOTES.

THE [illegible] BARIUM CO. are erecting a [illegible] brick warehouse, 60 by 120 ft.

THE NORTON EMERY WHEEL CO. are about to install [illegible] additional furnaces for the Baker-Bisson process, which will increase their capacity 50 per cent.

V. J. ROSSI has been running his electric furnaces during July and August, producing ferro-titanium alloy for experimental use in casting car wheels. During September operations will be discontinued, awaiting the results of the experiments.

THE CARBORUNDUM CO. are extending their furnace plant so as to increase its capacity 50 per cent. The new Acheson type furnaces will require an additional 1,000 horse power, and will be ready for operation as soon as the power company can furnish the power.

THE ELECTRICAL LEAD REDUCTION CO. are designing reduction apparatus for the whole of their large cell room, which has heretofore contained only one-tenth of its cell capacity, and expect before the end of the year to be running full capacity at a greatly decreased cost of operation.

THE NIAGARA POWER CO. have their first ten units of 5,000 horse power fully occupied, and several works are awaiting the opening of the new power house to enlarge their capacity. The next 10,000 horse-power of the new plant is being rapidly put in place, and October 10th is the date now set for turning on this current.

THE ACKER PROCESS CO. are erecting scrubbing towers at the works of their bleaching powder plant, to absorb the residual chlorine. The gases from the lime chambers carry out 0.01 to 0.05 per cent. of chlorine, which at present escapes into the air, but will in future be completely absorbed by passing through the scrubbing towers, where it comes in contact with coke saturated with water.

THE ACME FIBRE PRODUCTS CO. are erecting a two-story building, red brick two-story building, 50 by 120 feet, adjacent to the upper works of the Patterson Raceway Co. The building is to be used as a machine shop, to install the small choke coils which are required in each house numbers for the apparatus they use. The large 2,000 horse power plant which is in contemplation, and in which the apparatus is to be installed, will be [illegible] adjacent to the present plant on ground [illegible] for further extensions.

## DIGEST OF U. S. PATENTS PRIOR TO JULY, 1902.

*Compiled by Byrnes & Townsend, Patent Lawyers, National Union Building, Washington, D. C.*

This digest of electrochemical United States patents, prior to July, 1902, will be essentially one by classes, that is to say, it will set out for comparison those devices which have the same object, or those methods which seek the same result. In each class the patents will be arranged chronologically. It is the intention to make this digest complete in the sense of covering every point which is touched upon in the original specification. The first class to be dealt with comprises the patents on the electrolysis of sodium cloride with mercury cathodes.

271,900. February 6, 1883; A. L. Noll, Brussels, Belgium.

Gas retort carbon anodes slowly revolved over a quiescent layer of mercury, 1 cm. deep, resting on horizontal sheet-iron bottom of closed vessel.

Electrolyte, sodium chloride maintained saturated by crystals in perforated receptacles.

Amalgam drawn off while still fluid and distilled for sodium, or for rich amalgam, or converted into caustic soda by warm water.

307,463. November 4, 1884; A. S. Hickley, Montreal, Can.

A secondary battery with carbon anode, mercury cathode, sodium chloride or potassium chloride electrolyte.

Amalgam is formed in charging, chlorine escaping; in discharging, amalgam acts as anode.

Cell provided with incomplete partition at end, whereby part of the mercury may be withdrawn to regulate battery, or all may be separated from electrolyte to stop action.

307,462. November 4, 1884; A. S. Hickley, Montreal, Can.

Improvement on above.

Mercury contained in superposed stone trays and contact made by immersed wire netting.

Wooden grate in upper part of each tray supports a small stool, which serves to support and space the tray next above.

Anode-broken carbon packed around and between trays, contact being made by carbon rods.

Electrolyte sodium chloride solution.

350,040. January 25, 1887; A. S. Hickley, Montreal, Can.

Cathode mercury in depression in cell.

Anode, a carbon block above the mercury; supplemental anodes of broken carbon surround the mercury-containing depression.

Continuous flow of sodium chloride solution through cell and saturation chamber.

To remove amalgam employs a sieve; the thick amalgam is pressed to remove surplus mercury and packed in air-tight vessels. Subsequently used in primary or secondary batteries.

501,783. July 18, 1893; E. Hermite, Paris, and A. Dubosc, Rouen, France.

Mercury flows down over inclined surface of amalgamated copper, in close proximity to parallel platinum anodes.

Passes into trough, where it is allowed to stratify under carbon disulphide. Richer amalgam drawn off into separate vessel, decomposed by water and mercury returned.

Applicable to any solution of an alkali or alkali-earth metal, as Na, K, $NH_4$, Mg, Al.

In oxidizing, cell may form bases (with water), or any desired salt, as carbonates, by passing carbon dioxide through the water.

513,661. January 30, 1894; C. T. J. Vautin, London, Eng.

Finds that surface tension of mercury will prevent it from passing through perforations corresponding to 60-mesh sieve, if not subjected to shock and no considerable head.

Mesh of non-conducting material, as silk, perforated celluloid or vulcanite, or enameled metal, placed horizontally. Anodes at side and provided with chlorine-collecting hoods.

Sodium amalgam transferred through the mercury and oxidized by supernatant water.

Also oblique arrangement, the mercury cathode being arranged in terraces.

Also vertical arrangement, perforated or slotted iron plate, covered with vulcanized rubber. Mercury retained in perforations by mesh as above.

518,135. April 10, 1894; H. Y. Castner, London, Eng.

Apparatus for carrying out process of U. S. Patent 528,322.

Cell having two anode compartments and one intermediate cathode compartment, is supported on two adjustable knife edges and rocked by eccentrics.

For ⅛-inch depth of mercury the eccentrics have a pitch of about ¼ inch.

525,555. September 4, 1894; A. Sinding-Larsen, Christiania, Norway.

Mercury caused to flow by paddles through annular channel, passing at one point beneath a rotating anode, which is in an offset from central compartment, and separated from annular trough by incomplete partitions, the mercury acting as a seal.

Annular trough filled with water and central chamber with offset for anode with sodium chloride solution.

Cathode connections to mercury.

528,153. October 30, 1894; T. Drake, Huddersfield, Eng. Eng.

Porous pot closely wrapped with amalgamated wire gauze or equivalent cathode.

Anodes of carbon cast in lead cover in pot.

Sodium chloride solution in pot and water outside, both circulated.

528,322. October 30, 1894; H. Y. Castner, London, Eng.

Mercury cathode circulated (by pump or stirrer with radial blades) between anode compartment, containing sodium chloride solution, and cathode compartment, containing water.

Supplemental cathode and electrical connections to reduce the required electromotive force.

546,348. September 17, 1895; W. A. Rosenbaum, Montclair, N. J.

Body of mercury in annular trough. Annular bell, divided by transverse partitions, forming alternate decomposition and oxidation compartments, rests in trough, mercury operating to seal compartments.

Sodium amalgam formed in decomposition cells, annular bell rotated and amalgam oxidized by water.

May rotate bell continuously or oscillate.

Separate anodes and cathodes in oxidation cell, anodes being close to surface of amalgam to facilitate oxidation.

Ribs to retain mercury quiescent.

546,353. September 17, 1895; A. Sinding-Larsen, Christiania, Norway.

Vertical annular chamber contains rotating ring of amalgamated, tinned sheet iron, which, at lower portion, passes through the mercury cathode.

Center forms anode chamber, containing also feeding chamber.

Amalgam, as formed, is carried down through mercury by a small amalgamated roller, taken up by revolving ring and exposed to water in the annular chamber.

Automatic device for withdrawing caustic soda from latter at predetermined density.

Also a horizontal arrangement in which ring is conical, and amalgam is caused, by centrifugal action, to travel upward in a thin film.

[*The digest of the patents of this class will be continued in the next issue.*]

## THE NIAGARA FALLS MEETING OF THE AMERICAN ELECTROCHEMICAL SOCIETY.

The Niagara Falls meeting of the American Electrochemical Society, a full report of which is given in this issue, has proved the splendid success which had been hoped for. All who attended it will long remember it with pleasure, and we may hope that the success of this meeting will prove stimulating not only to the young society, which may well be proud of its work, but also to the great industry which the Society represents.

Swiftly advancing, indeed, like the electrochemical industry, has been the career of the American Electrochemical Society in the first half year of its life. Founded in Philadelphia on April 3, 1902, it is just six months old; it has now more than 400 members, and has held two general meetings, both of which were extremely well attended; at these meetings there were read and discussed together about 40 papers on various important and interesting subjects. There were well-meaning scientists and engineers who first opposed the foundation of this new society as being superfluous and detrimental to the interests of the older sister societies—the American Institute of Electrical Engineers and the American Chemical Society—and it is a splendid proof of the value of the young society's work that its strongest former opponents now join it and confess that the new society fills a need.

The American Electrochemical Society has certainly secured members from both the other societies, without being detrimental to their interests in any way—on the contrary, while the watchword of the new society is naturally differentiation and specialization on the distinct limited field of electrochemistry, it has broadened the mind of both electrical engineers and chemists; it has brought them together, and it is, indeed, now the connecting link between the American Institute of Electrical Engineers and the American Chemical Society. By attracting the best members of these two societies and bringing them into personal contact with each other, it stimulates original thought on new lines; surely, the electrical engineer can always learn something from the chemist, and vice versa. But besides this, the American Electrochemical Society has brought together the electrochemical specialists of industry and science and the exchange of opinion between both classes of electrochemical workers has already proven to be of considerable value to both.

The quality of the papers read at the two meetings has been unexpectedly high. Electrical engineers, chemists and physicists of established reputation have contributed papers; and with them there are the young, energetic electrochemical workers pushing to the front. Youth is, indeed, the keynote of the success of the new society. It is only natural that in such a young industry and science there is no uniformity of opinion; there are no standardized methods, and there is no

orthodox faith. It would be an unfavorable symptom if it was different. Just for that reason, it is of the highest importance that there should be animated discussion, there should be freedom of speech even if sometimes a speaker hurts the scientific feelings of others, by attacking their pet theories. The American Electrochemical Society is no mutual-admiration society; it is a society to exchange views, to disseminate among the members all the information known, and to stimulate new thought and new work. In regard to the discussion of the papers, there is room for improvement; the value of the discussion would be considerably enhanced if the papers were printed and distributed in advance of the meeting, so that it would be possible for the members to study them carefully and prepare what they have to say in the discussion. We understand such a plan has already been taken into consideration by the board of directors of the Society, and we trust it will be carried into effect. Surely the money spent for this purpose will be well spent.

Lack of space does not permit here a detailed analysis of the papers read at Niagara; longer abstracts of all of them will be found on the following pages. It may suffice to say here that at both meetings, at Philadelphia and at Niagara Falls, the programme contained papers on subjects of the greatest variety; indeed, in looking over the titles, one is astonished to find how large the field of electrochemistry really is. While professors and scientific workers are slightly in the majority, it is extremely gratifying to see that the practical electrochemical engineers also have contributed their share, and have not hesitated to describe their processes and to tell of their troubles.

Before the Society was founded, the opinion was repeatedly expressed that the secretive methods of the electrochemical manufacturer would be the stumbling block; that the practical engineer might become a member, but would never read a paper. It affords great satisfaction to state that this fear was unfounded. An unexpectedly large number of papers have been read at the two meetings by industrial electrochemists; all of these papers proved to be of great interest, and will form a very valuable part of the transactions of the Society. It is gratifying to see that the practical engineers themselves recognize that a frank statement of what they are doing can never hurt them. Publicity always has been and will be a spur to progress. In this connection we may mention here the names of those electrochemical companies which courteously opened the doors of their workshops to the members and guests of the Society. They were: The International Acheson Graphite Co., the Carborundum Co., the Electrical Lead Reduction Co., and the Atmospheric Products Co.

It is also gratifying to see that the subjects of the papers read and discussed at the meetings were not limited to electrochemistry in the narrowest sense, but repeatedly dealt with problems of physical chemistry. Indeed, an electrochemical problem is often only a special case of a more general problem of physical chemistry. This is why the pioneer society in the field of electrochemistry, the old German Electrochemical Society, has recently changed the name into German Bunsen Society for Applied Physical Chemistry. Nobody would probably recommend an analogous name for the American Electrochemical Society. But the policy is to be recommended, not to exclude the discussion of problems of physical chemistry. For the electrochemist needs knowledge of the principles of physical chemistry, and it is the duty of a society devoted to the interests of electrochemistry to acquaint its members with the great problems of physical chemistry in general, which may have an important influence on the developments of industrial electrochemistry in the future.

Finally, we may say that a good deal of the success of the new Society has naturally been due to the personal and social element, and to the free intercourse between the members. It is perhaps not accidental that the Society was formed in Philadelphia. The old Quaker city is often called the city of the homes. Electrochemists in Philadelphia first felt that, as electrochemists, they had no home; that, as electrochemists, they were not at home in any of the old large national societies. And when they appealed to the electrochemical engineers and scientists of the country, the hearty and enthusiastic response from all sides disclosed the fact that this was a general feeling all around. The electrochemical engineers and scientists, representing a rapidly-progressing industry and science in the strength of its youth, wanted to have a society for themselves. Thus the American Electrochemical Society was founded. While the social intercourse at the Philadelphia meeting was very pleasant, and many workers in the electrochemical field came there for the first time into close contact with each other, the Niagara Falls meeting was a still greater success in this respect. At Niagara Falls all electrochemists naturally felt that they were at home, and much credit is due to the untiring efforts of the local entertainment committee. On the walks to the Falls, on the visits to the plants, on the trolley trip and the banquet many new acquaintances were formed; and no young electrochemist, who is proud to be an electrochemist, will ever forget the days when he could shake hands with such pioneers as Mr. Acheson, Mr. Bradley, Mr. Cowles and Mr. Hall. There was good will and good feeling all around, and we trust that it may always be so in the American Electrochemical Society.

## AMERICAN VERSUS GERMAN PRACTICE.

A certain conversation between two members of the American Electrochemical Society at the recent meeting at Niagara Falls was such a good illustration of one of the characteristic differences between American and German practice, that it seems worth while to call attention to it here, especially as we Americans are sometimes criticised rather severely by our foreign colleagues for doing things in a crude way.

While inspecting one of the interesting electrochemical processes, a member of German descent remarked, with great pride, that a certain German company, which had done this same thing fifteen years ago, had obtained a far greater percentage yield of the desired product; to which an American member replied, "and that is no doubt the very reason why the German company failed to make it a success, while the American inventor succeeded." With characteristic German thoroughness, the thing which seems to have been most prominent in the mind of the German experimenter was to get the greatest

possible percentage yield, and after he got the most he could he found that the process was too expensive. The American, however, attacked the problem in a more practical way; what he tried to get was at what percentage yield is the total cost of the desired ultimate product the least. This is certainly the proper way to consider a commercial proposition. In doing this he found that at a very poor yield the final product became quite cheap, while the German had blindly passed by this successful point in his efforts to get as near the theoretical perfection as possible.

As success is what most of us are, or should be, striving for, it seems to be more creditable to succeed in making practical and useful a theoretically-imperfect process, than to make it so perfect theoretically that it becomes useless, and a practical failure. The Germans may answer to this that it depends upon whether one is working for "glory" or for "money;" but is there not also "glory" in succeeding to develop something that is useful to the world at large? Is it not sometimes even greater than the credit of having developed a useless process to high theoretical perfection? We have great respect for the thorough, indefatigable work of the Germans, but we think that they are too apt to fail to appreciate that it also involves ability, patience and hard work to reduce things to practice.

Suppose the development of the electric light had been abandoned in its early days on the ground that it was theoretically extremely imperfect, having a light efficiency of only a few per cent.; we would, then, be still limited to gas and oil, as we were twenty-five years ago. There are other occasions like this in which wastefulness is economy.

Concerning the process above mentioned, it was very interesting and instructive to notice that in the experimental researches to determine the best values of each of a number of factors in the process, one of the co-ordinates in the curves of results was always the cost per pound of the ultimate product, or some similar factor. This, we think, is an eminently practical and the safest and most direct way of finding the best working conditions, and one which might well be followed by others who are searching for the lowest cost of production.

## ELECTROLYTIC PRODUCTION OF SODA WITH MERCURY CATHODES.

In the present issue we complete the presentation by abstract of the patented forms of electrolytic cells operating through the intermediary of a cathode of mercury to convert solutions of brine into caustic soda. Commercial success here, as always, has been a beacon which has attracted hosts of inventors, and here, as always, there is no single expression for the character of the inventions. The Patent Office is an indiscriminate collector, making no distinctions along the lines of relative value, but insisting only that there shall be no duplicates in its cabinet.

Through the wide diversity of forms there runs, however, a clear and almost vital distinction, the character and aspect of which seems to be little understood, even among workers in the field. This distinction hinges upon the quantity of energy represented by the decomposition, which is dependent upon whether or not the chemical energy of the oxidation of the sodium is transformed into electrical energy and turned into the electrolyzing circuit. If the oxidation of the alkali metal be effected by means of a "combining circuit"—in other words, if the mercury acts in whole or in part as a bipolar electrode between independent anodes and cathodes—the energy of this transformation is more or less conserved. If, on the other hand, dependence is placed on local action or area of contact for insuring a rapid denudation of the amalgam, the voltage theoretically required for the decomposition is considerably increased. If the surface at which the oxidation of the sodium occurs is not an active electrode face, it becomes immaterial, electrically, what separation, in space or time, may exist between the act of forming the amalgam and its decomposition by water.

## THE ST. LOUIS WORLD'S FAIR OF 1904.

The Electrical Department of the St. Louis World's Fair has a very energetic director in Professor Goldsborough. At the Niagara meeting of the American Electrochemical Society he made a strong appeal to the electrochemical manufacturers, and, we hope, it will have the desired effect. It is high time to show before the country and before the world the advances of American electrochemical industries. It is sometimes astonishing to find how little the general public knows of electrochemistry and electrometallurgy. Everybody knows aluminum, but very few know how it is made; in fact, the general public is absolutely ignorant of the nature of electrochemical processes. These conditions should certainly be changed in view of the fact that the value of the output of the electrochemical industries in the United States is at present estimated at about $100,000,000 per year.

The general public cannot be blamed for its ignorance. People have never had an opportunity to see electrochemical processes in operation; of course, they all know and use products of electrochemical industries, but while seeing and using the finished product, they do not know anything about the method by which it is made. Even the finest display of finished products of electrochemical and electrometallurgical industries would not teach the general public anything concerning the methods and possibilities of electrochemistry. To interest people in electrochemistry, it is necessary to show them by an object lesson how electrochemical processes are being worked. Director Goldsborough hits the point in urging manufacturers to exhibit model plants and to show processes in operation.

Director Goldsborough also meets at once a difficulty which seems to be in the way of the fulfillment of his plans. It is a fact that electrochemical manufacturers generally do not want to say or show anything about their methods. Professor Goldsborough points out correctly that manufacturers are not expected to show their trade secrets before the public. What they are urged to show are the general principles of their processes in operation—even if the details of working in the model plant exhibited differ greatly from the methods employed in the industrial plant. If the general public can thus be educated in the general nature and the unlimited possibilities of electrochemical and electrometallurgical processes, an advance of industrial electrochemistry is bound to follow, in comparison with which the progress made in the last ten years may appear slow.

## THE EFFICIENCY OF ELECTRIC FURNACES.

In the following we give an abstract of the recent American Electrochemical Society paper by Dr. J. W. Richards on this subject:

An electric furnace is a furnace for accomplishing a physical or chemical change in materials by means of the agency of heat, said heat being supplied by the transformation of electrical energy. The cases where electrolysis take place in fused electrolytes, are left out of consideration, because they are essentially electrolytic processes in which the heating of the current is unavoidable and incidental to the main process of electrolysis and must be excluded from the term "electric furnace processes," if that term is to retain its individuality and stand for a definite class of operations. If this limitation is understood, the output of an electric furnace is more or less proportional to the amount of heat energy developed in the furnace. It is necessary to say "*more* or *less* proportional," because, although the amount of heat necessary to produce the change in a given amount of material may be a perfectly definite quantity, yet the proportion of the heat developed in the furnace which is actually absorbed or applied in producing this change is a variable one, being always less than 100 per cent., and frequently very much less. The proportion of the heat energy of the electric current thus applied to producing the useful change in the charge is called the *efficiency* of the furnace.

The usefully applied heat will include one or both of two factors. The first is the amount of heat necessary to heat the charge up to the temperature of the furnace. The second is the heat absorbed in chemical reactions between the constituents of the charge when they are heated to the reacting point. This second part of heat can be calculated from thermochemical data, while the former part of heat—that required for the purely physical changes—can be calculated from the mass of the charge, the specific heats in the solid and liquid states, the latent heat of fusion and the temperature of the furnace.

The efficiency of an electric furnace operation depends on many factors, among which are the following: size of furnace, temperature of reaction, protection from radiation, management of the terminals, feeding and tapping, general management. Of these the most important, in commercial practice, is the size of the furnace. The volume or contents of a furnace increase approximately as the cube of the linear dimensions, while the radiating surface which conditions the loss of heat, increases as the square of the linear dimensions; therefore the proportion of radiating surface to unit of contents *decreases* approximately in proportion as the linear dimensions are increased. It is probable that if a 100 horse-power electric furnace works at an efficiency of 50 per cent., with the other 50 per cent. lost by radiation and conduction, then an 800 horse-power furnace of the same design, working the same process at the same temperature, should give an efficiency nearer to 75 per cent. Most of the desiderata of commercial success of electric furnace work lie in the direction of increasing the size of the furnaces to the furthest limit set by mechanical or physical considerations.

While electric furnaces are generally classified into the resistance type and the arc type, it is better for the present purpose of calculating the efficiency to use a different classification. All furnaces are divided into two large classes. The first class includes those furnaces in which the charge is simply heated without any *chemical* change taking place; the second class includes those in which besides the heating of the charge there is also a chemical change. Each class may be again subdivided into two subclasses, according to whether the heating takes place with or without a melting or fusion of the charge.

*Heating with at Fusion and without Chemical Change.*—An example of this is the conversion of anthracite coal into graphite in the Acheson furnace. It is true that some chemical changes probably occur during the conversion, such as the progressive formation and decomposition of carbides, but these are negligible because their plus and minus heat quantities neutralize each other; the change from amorphous carbon to graphite is a heat *evolving* reaction and therefore must be reckoned as really *assisting* the current or, practically, diminishing in our figuring the calculated efficiency. The data are as follows: 1,000 horse-power, in twenty hours, convert 12,000 pounds of anthracite into 10,000 pounds of graphite. The heat gained in conversion into graphite is about 10 per cent. of the heat supplied by the current; hence the real amount of heat is 110 per cent. of the heating power of the current; of this 82.5 per cent. are utilized, giving an efficiency of $82.5 \div 110 = 75$ per cent. In the Acheson process of graphitizing electrodes by placing them crosswise, embedded in a resistant material, 1,000 porse-power graphitize 7,000 pounds of electrodes, embedded in 7,000 pounds of granular carbon and lining; the net efficiency of the operation is 38 per cent.

*Heating with Fusion, but without Chemical Change.*—The Jacobs process of fusing calcined bauxite is an illustration. The process is simple fusion by the arc, in a cylindrical pot. With a charge of 3,000 pounds the efficiency is 74 per cent.

*Heating without Fusion, but with a Chemical Change.*—The manufacture of carborundum is a good example. A mixture of carbon, silica sand and salt is heated by the incandescence of a conducting carbon core, until the salt is volatilized carrying off most of the metallic impurities as chlorides, the silica is reduced and combines with the excess of carbon present to form silicon carbide. The furnace is 20 feet long, and 1,000 horse-power is passed through for thirty-six hours. The calculation of the efficiency gives 76.5 per cent.

*Heating with Fusion and with a Chemical Change.*—An example is the production of calcium carbide, for which the calculation gives a net efficiency of 62 per cent. There is, however, a distinct experimental gap in the lack of knowledge of the specific heat of such products of the electric furnace, at high temperatures. When these are known, calculations of the efficiency can be made with much greater exactness.

The net result seems to point to a commercial efficiency of 60 to 75 per cent., calculating with furnaces of 200 to 1,000 horse-power. It seems that furnace operations which involve a heating effect only, without any chemical change, give a higher efficiency in general than those in which a chemical change is also involved. The value of such approximate figures is that any one starting an electric furnace operation should be able to calculate the approximate output to be expected, or, if planning or designing for a given output, will have a guide to indicate the approximate size and capacity of the furnaces needed.

---

## CATHODIC REDUCTION.

In his American Electrochemical Society paper on this subject, Alfred T. Weightman, of the Electrical Lead Reduction Co. of Niagara Falls, brought out several points which are interesting from a theoretical point of view, and at the same time of practical importance for the electrochemical engineer.

The result of the electrochemical action at a cathode is always reduction—either of ions in the solution, or of the electrode itself. In the first case, that of the reduction of ions, the problem becomes complicated if there are several kinds of cations in the solution which can be reduced; *i. e.*, if we have a mixture of several electrolytes, for instance $ZnCl_2$ and $Cu\,Cl_2$. Both the Zn and Cu ions are active in transporting the current through the solution; but this does not mean that both must be reduced or deposited upon the cathode. The principal factor which determines the kind of ion to be deposited is, of course, the heat of formation of the different possible reactions: that reaction which absorbs the least energy occurs, in general, most readily; but this statement is only approximately true. The concentration of the two electrolytes and the current density must also be taken into account.

In the second case, that of the reduction of the cathode itself, the cathode is usually a compound of a metal, and the cations (usually H ions) combine with the non-metallic radicle forming a new compound. The best known example is the reduction of the negative plate of a storage cell during charge, from lead sulphate to metallic lead. In this case the cathode consists partly of sulphate and partly of metallic lead (the grid or active material which has already been reduced); hence the two following reactions are theoretically possible: first, the evolution of hydrogen at the metallic lead; second, the reduction of sulphate to lead. From the thermochemical data it appears that the reduction of the sulphate requires a slightly higher voltage than the liberation of hydrogen. It is, therefore, astonishing that not more hydrogen is evolved from a negative plate during charge than is actually found to be the case.

In the Salom process of the electrolytic reduction of galena to metallic lead the reactions are similar. PbS is reduced to Pb, and $H_2S$ is formed. But on considering the heat of formation of the two possible reactions (evolution of hydrogen or reduction of galena), they are found to lie even farther apart than in the case of the reduction of lead sulphate in the storage battery. The author has made a very large number of experiments with a view to producing as small an evolution of hydrogen as possible, or, in other words, raising the current efficiency as high as possible, so as to reduce the largest quantity of galena for a given current. The author has found that the efficiency is extremely sensitive to the degree of purity of the ore and the nature of these impurities; to the conductivity of the ore; to the fineness of grinding; to the strength and purity of the electrolyte; to the thickness of the layers of ore; to the temperature of the solution, and various other causes—but strange to say, it is almost unaffected by the current density used. The author exhibited several curves and tables, showing the results obtained with various current densities; the similarity in the shape of the curves under different current densities is remarkable; in fact, the numbers of amp. hours required for a given percentage of sponge in the ore agree within the limits of experimental error.

As noticed above, the reaction $PbS + H_2 = Pb + H_2S$ requires a very much higher absorption of energy than the mere liberation of hydrogen; and yet, under proper conditions, the former reaction, which is the one that is wanted, can be kept up to an efficiency yield of 80 per cent., or over, for two-thirds of the reduction, even when the galena is present to the extent of only 25 per cent. On the other hand, it is all the more disappointing that the reaction cannot be brought to a completion, as the last 5 per cent. of PbS cannot be reduced. This, of course, necessitates further treatment to obtain a pure product.

The author has also made experiments concerning the reduction of other sulphides. He used $Cu_2S$ and NiS; the results obtained are quite different from those for PbS.

For the explanation of the phenomena, the author refers to Caspari's theory of the overvoltage (Ueberspannung). According to this there is a certain overvoltage required to evolve hydrogen, and this overvoltage is different for different materials of the cathode. This overvoltage may account for the results, unexpected from the thermochemical data.

## STORAGE-BATTERY INVENTION.

In an American Electrochemical Society paper on this subject, Hugh Rodman discussed the prospects of the Edison battery in comparison with the lead cell.

The author first discussed some general requirements which must be fulfilled in a commercial battery, and which greatly limit the number of possible combinations. A commercial cell must be able to stand an overcharge; and when it is being overcharged, there should be unchanging electrodes in an unchanging electrolyte; the author shows that this requirement reduces the list of available anodes and electrolytes to lead in sulphuric acid and nickel in alkali hydroxide. This does not mean, however, that the active material must necessarily contain nickel or lead, but simply that the grid must be one or the other of these metals in its appropriate solution. If permanency only is considered, the active material of the "oxygen plate" may be any insoluble oxide or salt; while the grid and active material of the "hydrogen plate," putting aside as impracticable any dissolving material such as zinc, may be either of the same metal as the oxygen plate, as lead in sulphuric acid, or else of some other metal soluble only at the end of a complete reversal of current, as iron in hydroxides. Practically, the whole problem is thus reduced to two classes: first, lead peroxide and spongy lead upon lead plates in sulphuric acid, *i. e.*, the common lead cell; second, mercuric or nickel peroxide upon nickel plates, together with cadmium, nickel or iron sponge upon iron or nickel plates in an alkali hydroxide, *i. e.*, the Edison battery. As the most promising example of the latter type he considers the Edison nickel iron cell and compares it with the ordinary lead cell, concerning the grid, the active material, the electrolyte, and in general.

Concerning the grid the author remarks that the alkali battery has the great advantage of having its support plates of a stiff, easily-worked metal.

Concerning the active material he points out that lead peroxide is a conductor, while nickel peroxide is not, and so must be held in close contact with some conductor itself inactive, as nickel or carbon. Edison packs the active material with powdered or flake graphite, held rigidly in a perforated box. An objection to this is that the dense active mass impedes diffusion. An advantage is that the close-held mass, with its stiff, finely-perforated cover, is apparently not subject to deterioration.

Concerning the electrolyte there is a great difference between the two types of cells. In the acid battery a mass of electrolyte is required, large enough to hold both the acid needed for the reactions and enough over to insure low electrolytic resistance at the end of the discharge; in the alkali battery only enough electrolyte is required to make a bath for the current. While this is one of the most important factors in making the alkali cell light, it adds greatly to an already serious trouble: refilling. Here the alkali cell is inferior to the lead cell. First, the overcharge is greater, on account of the more difficult diffusion. Second, the current is greater for the same energy output. Third, the alkali cell has comparatively a small mass of electrolyte to draw upon. The author thinks that in all, the question of the mass of electrolyte comes to this: that "in the alkali battery we multiply a serious trouble by a factor of three or four, and then halve the means of getting around it." Another trouble arising from refilling is the quality of water used in practice. If the hydrant is the source of supply, it may be the means of putting into the electrolyte some active agent that eventually disintegrates the plates. Again, the acid electrolyte is commercially the better for the ease of handling. Finally, the author thinks, that a battery with unchanging electrodes and changing electrolyte would, in many ways, be better than its opposite; for instance, the change of electrolyte density is, in the lead cell, a very useful means of determining the state of charge and discharge.

Concerning the uses of the storage battery, the author believes that for central station work, which at present takes about 75 per cent. of the battery output, the position of the lead cell seems secure, while for lighter service, particularly for automobiles, where watt efficiency and cost are to some extent subordinate to convenience, the choice will depend largely upon capacity and reliability. Exact data on the alkali cell are wanting and must be wanting until the cells are put into ordinary service with ordinary care and attention; it seems certain that the necessity for frequent refilling will mean trouble and irregularity of working, while the problem of handling the alkali electrolyte and excessive gasing will need most careful consideration.

The author states that the commercial life of lead plates in truck or cab service is about 15,000 to 20,000 miles for negatives, 12,000 miles for Plante positives, and 6,000 miles for pasted positives. In other words, a 4 or 5 ton truck running 20 miles per day for 300 days in a year requires new positive plates once in a year, or once in two years, according to the type of plate used. Cabs and lighter wagons have about the same life with a capacity of 40 to 100 miles on one charge. Under these conditions experience has shown that the electric wagon gives better city service than can be gotten from gas or steam or horse. If a better battery than the lead cell was available on the market—either an improved lead cell or a better new one—it would control practically all city traffic not on rails.

## ELECTROLYTIC DISSOLUTION OF SOLUBLE ANODES.

In a paper read before the American Electrochemical Society, Woolsey McA. Johnson made an attempt to co-ordinate the different factors which are of influence in the electrolytic dissolution of soluble anodes consisting of an alloy of different metals. In some respects his problem is the anodic analogon to the problem of cathodic reduction, dealt with by A. T. Weightman.

The fundamental facts upon which Mr. Johnson bases his theoretical considerations, are as follows: Every metal has a certain specific "electrolytic tension," or potential difference against an electrolyte, this potential difference depending on the nature of the electrolyte and the general physical conditions. Every metal has a specific electrical conductivity. These two properties—potential difference and conductivity—are profoundly modified by alloying with other metals. On these resulting properties of alloys segregated in the anode, depends the selective electrochemical dissolution of the anode.

In most cases alloys are formed with the evolution of heat; the resultant product is harder and has less tendency to dissolve. Further—and this is of greater importance—with the exception of several metals as zinc and cadmium, two metals unite to form an alloy the electric conductivity of which is smaller than that of either.

If, for instance, a particle of silver-copper alloy is considered which is surrounded by pure copper crystals; as the alloy has a much lower conductivity, it is to be expected that the current is shunted around the silver-copper alloy and finally dissolves its copper backing; it then can be brushed off into the "slime." On the other hand, if a "bi-metallic" anode is used, *i. e.*, a sheet of copper, by the side of which is a sheet of silver one two-hundredth of the size, it will be found that the silver dissolves at a much lower current density than in the case of the alloyed anode. The only difference in both cases is that in the first the silver is alloyed with the copper and not in the second.

Arsenic and antimony, if present as metals besides copper, would have a greater tendency to dissolve than copper, on account of their high electrolytic solution tension. But, in practice, for the same reasons which were just explained, they pass into the slime directly from oxidized anodes.

The author believes that much can be saved in copper refining by previous treatment of the anodes. A careful metallographical examination of the anode and some little thought on the alloys that can be formed, will reduce any electrorefining proposition to its simplest terms.

## ON THE THEORY OF THE ELECTROLYTIC RECTIFIER.*

By Prof. K. E. Guthe.

An explanation of the peculiar phenomenon that an aluminum plate immersed in an alum solution will allow a large current to pass in one direction, but only a very small one in the other, may be attempted from two different points of view. First, we may assume that the current, when the aluminum plate forms the anode, produces a non-conducting film *i. e.*, introduces an ohmic resistance, while this film breaks down with the current flowing in the opposite direction. Moreover its resistance must vary with the current strength, because it decreases apparently as the current towards the aluminum increases, *i. e.*, we have here an exact analogy to the so-called "resistance of transition," formerly supposed to exist in ordinary electrolytic cells.

The other point of view starts with the assumption of a very high electrolytic polarization (25 to 30 volts). According to this the ions are prevented by some cause, whatever it may be, from reaching the electrode and from giving up their electrical charges, unless they have obtained a certain amount of energy enabling them to overcome the obstacle. In favor of this latter conception—though the two do not necessarily contradict each other—may be mentioned, that a decrease in the size of the plate does not appreciably alter the current as we should expect, if the resistance were ohmic in its character.

So far the whitish, non-conducting oxide or hydroxide film on the plate has been held responsible for the formation of this high apparent resistance. But since no change can be found in the film under different conditions, and, since the resistance returns with remarkable regularity to the same value for the same current, the author considered the assumption of the formation and subsequent breaking down of the film as improbable.

He brought the plate, on which a high resistance had been produced, into a vacuum and found that a large number of minute gas bubbles appeared at the plate, showing the presence of a gaseous film. Removing this, at least partially, under the air pump, the resistance of the plate was greatly reduced.

The explanation given for the behavior of the aluminum rectifier is, then, that with the aluminum as anode the oxygen gas formed is kept in the meshes of the solid oxide film and thus prevents the passing of the ions, until by increasing the potential difference at the terminals of the cell, the energy of the ions is raised sufficiently to break through the gaseous film. On the other hand, the hydrogen produced by the current when flowing in the opposite direction is not held back in the solid network, but escapes freely. Consequently, we have no high resistance when the aluminum plate forms the cathode.

Some experiments were undertaken to prove the conclusions to be drawn from this theory. Increase of temperature decreases the apparent resistance. The concentration of the electrolyte does not influence the phenomenon. Different electrolytes depositing oxygen at the plate—solutions of alum, rochelle salt, ferrocyanide of potassium, copper sulphate and zinc sulphate—show all the same behavior. Anions, as chlorine, will not produce the high resistance, since they act in the same manner as hydrogen.

Since we have here a kind of a semi-permeable membrane, the author has examined the well-known membrane of copper ferrocyanide, deposited in a porous cup, and found it to act qualitatively the same way as the aluminum plate. In a cell, formed by copper, solution of copper sulphate, membrane, ferrocyanide of potassium solution, platinum—only a small current could be obtained in the direction from the copper to the platinum, the counter e. m. f. of polarization rising as high as 20 volts, while the current would pass unobstructed in the opposite direction. A film deposited on a copper plate immersed directly in a solution of potassium ferrocyanide behaved in the same way.

In conclusion, it was pointed out that this theory might be able to explain ordinary polarization by the assumption of a liquid high-resistance film—possibly pure water—between the electrodes and the electrolyte; an explanation which would also facilitate our understanding of the peculiar fact, that hydrogen polarization appears to have very different values accordingly as it is deposited on platinum, lead or mercury.

*Abstract of a paper read before the A. A. A. S. at the Pittsburg meeting, July, 1902.

# NIAGARA AS AN ELECTROCHEMICAL CENTRE.

## THE ELECTROCHEMICAL INDUSTRIES OF NIAGARA FALLS.

By Joseph W. Richards, Ph.D.

*President of the American Electrochemical Society*

*(Concluded)*

### The Pittsburg Reduction Co.

THIS company were organized in 1888, by the late Capt. A. E. Hunt, to work the Hall process of producing aluminum. The chief investors were the Mellon Bank of Pittsburg and Messrs. Hunt and Clapp, of the Pittsburg Testing Laboratory. At present, R. B. Mellon, of Pittsburg, is president; Charles M. Hall and G. H. Clapp, vice-presidents; Arthur V. Davis, secretary and general manager. Originally, $20,000 was subscribed to start the company, but at present the capitalization of the company is $600,000 of 6 per cent. preferred stock and $1,000,000 ordinary stock, paying 8 per cent Mr. Hall lives at Niagara and has charge of the operation of the Niagara works.

There are two plants of this company at Niagara: the upper plant, situated on the grounds of the Niagara Falls Power Co.,

UPPER WORKS, PITTSBURG REDUCTION CO.

above the falls, and using 4,000 horse-power; the lower, situated on the edge of the gorge below the falls, and taking 6,500 horse-power from the Hydraulic Power and Mfg. Co.

The upper plant is situated half a mile above the upper power house, on a 10-acre plot of ground, and was the first plant to utilize this upper power. When, in 1893, the Niagara Falls Power Co. completed their power house, the next step of finding customers for the power was not easily solved, and special inducements were made to the Pittsburg Reduction Co. to break the ice and become the first plant to utilize this power. The offer took the shape of a contract to furnish the direct current needed for the process, at a certain price per horse-power per year, which price is a private matter between the two companies, but is understood to be not over $18 per horse-power-year. This necessitated the installation by the power company of transformer machinery, at the reduction plant, which is owned and operated by the power company. This is, as far as is known to the writer, the only case in which this power company have furnished the current transformed to suit the customer's purpose, all subsequent contracts being at $18 to $20 per horse-power per year for the alternating current at 2,250 volts, the purchasers putting in and operating their own transformer machinery.

The alternating current is first passed through a set of twelve air-cooled stationary transformers, which reduce its potential to 115 volts and raise its ampérage correspondingly, with a loss in conversion of 3 per cent. It then passes to rotary transformers, of which there are six each of 800 horse-power, which transform the alternating current of 115 volts into direct current at 160 volts, with another loss of 3 per cent. in conversion. Five of these, run to full capacity, furnish two currents of approximately 10,000 ampères by 160 volts each; sometimes all six are run, at five-sixths full capacity, to furnish the same current.

Each current passes through a line of reducing pots, being conducted on aluminum bars, 12 inches by 1 inch, giving a carrying capacity of over 800 ampères per square inch of conductor. The bars are not insulated, the low voltage rendering that unnecessary. The voltage drop at each pot is a little over 5 volts, each pot absorbing about 65 horse-power. The current passes into each pot through carbon electrodes, 3 inches diameter by 18 inches long, each carrying 250 ampères of current. It is found that this is about the maximum current which can be carried by the copper-rod connections without undue overheating. About one-half the energy of the current is absorbed in the chemical work of decomposing alumina, the other half is converted into heat and keeps the bath at the proper temperature and fluidity necessary for electrolysis—about 850° to 900° Centigrade. The efficiency of recovery reckoned on the ampères used is between 80 and 90 per cent. The bath is the ordinary Hall bath, containing cryolite, to which is added aluminum fluoride, as the solvent, and with alumina dissolved therein. The action of the current sets free aluminum and oxygen, the latter uniting with the carbon anodes to carbonic oxide. Although 4,000 horse-power are being used, the smell of fluorine is usually not perceptible in the pot room, except during casting or trimming up a pot. The aluminum obtained averages 0.1 per cent. iron, 0.3 per cent. silicon, with smaller amounts of copper, titanium, carbon and sodium, but is guaranteed over 99 per cent. pure, averaging more nearly 99.5 per cent. The selling price of such metal is, in ton lots, 31 cents per pound; less pure metal is made from less pure alumina, and sold, for use in casting iron and steel, at 2 cents per pound less.

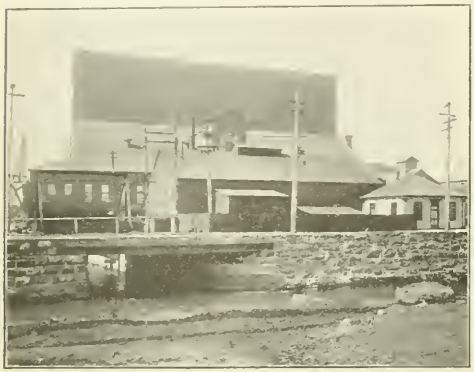
The main reduction room is an iron building, 180 by 85 feet, with a high roof. The windows are whitened by the hydrofluoric fumes occasionally escaping, but the fumes in the building are seldom strong enough to be perceptible. The metal is run into rough ingots, weighing 20 pounds each, and the total output from this plant must be in the neighborhood of 7,200 pounds daily. The crude ingots are shipped to New Kensington, Pa., to be remelted and converted into commercial shapes.

Alongside this main room is a building of equal area, but not so high, in which are kept the stock of metal, and also stocks of alumina and carbons. It contains furnaces for baking the carbon lining in the pots, and machinery for drilling and repairing the carbon electrodes. There is also a well equipped laboratory, presided over by Wm. T. Whitten, with several assistants.

The company own large deposits of bauxite, the native hydrous aluminum oxide, in Georgia and Alabama.

In 1900 Mr. Hall invented an entirely new method of commercially purifying alumina (U. S. Patents 677,207, 677,208, 677,209, of June 25, 1901), which will receive its first commercial application at Niagara Falls. The bauxite is mixed with sufficient reducing agent, such as carbon, to reduce all the impurities in it to the metallic state, *i. e.*, silica to silicon,

titanic oxide to titanium, iron oxide to iron. The mixture is then melted up in electric furnaces, using a carbon pole, the material itself being fed into the arc and the melted alumina constituting the other pole. An alternating current of low voltage is used. The impurities collect as a metallic alloy of iron, aluminum and silicon, while the purified alumina above is almost chemically pure. The furnace is let cool and the contents separated when cold. It is estimated that in this way the bauxite can be purified at less cost than by the wet, chemical processes. The alumina produced is granular, heavy, dissolves well in the pots and produces a metal of high purity.



LOWER WORKS, PITTSBURG REDUCTION CO.

The lower plant of the Pittsburg Reduction Co. is situated on the edge of the gorge, one-quarter mile below the steel bridge, and immediately above the power house of the Hydraulic Power and Mfg. Co. The current is generated in the power house, as direct current, by means of Westinghouse dynamos of 750 horse power each, coupled direct to turbines with horizontal shafts, the current being conveyed on aluminum cables, of 28 square inches sectional area, a distance of 250

THE CARBORUNDUM CO.

feet to the reduction room on the bank. Each dynamo gives a direct current of 2,000 amperes, at a potential of 280 volts, and nine such machines furnish the 6,500 horse-power necessary to run three lines of pots (2 lines are run at the upper works by 4,000 horse-power). The method of reduction is exactly the same as at the upper plant, and the output approximately 50 per cent. greater, making the total output of both plants probably 19,000 pounds per day. The building has its roof extended into an enormous ventilator, giving it the appearance of a grain elevator, but this greatly increases the comfort of the workmen. No other work than reduction is performed here, for which a force of about 150 men, working in eight-hour shifts, suffices. At the upper works the force is about 200.

Besides these works this company have recently extended their plant by the installation of 5,000 horse-power at Shawinigan Falls, Quebec, and the acquisition of 12,000 horse-power and 100 acres of ground at Massena, N. Y., on which an aluminum plant will be erected. Our congratulations to the enterprising pioneers of the aluminum industry in America!

### The Carborundum Co.

This company also owe their organization to Pittsburg capitalists, who in 1893 organized them to work the processes of A. G. Acheson for producing carborundum. The present officers are: F. W. Haskell, president; F. J. Tone, works superintendent, and among the larger stockholders are A. W. and R. B. Mellon, Pittsburg; A. G. Acheson and G. R. Rayner, Niagara Falls.

Carborundum is carbon silicide, CSi, and is formed by intensely heating, in an electric furnace, a mixture of carbon, sand and salt. Mr. Acheson first made it while trying to melt

A CARBORUNDUM FURNACE.

carbon and clay together, and to crystallize out the carbon, and obtaining some bright blue crystals in this manner, which were certainly not pure carbon, he suspected that they were a compound of carbon and alumina, and constructed for them the name *carborundum*. Analysis, however, showed these crystals to contain 60 per cent. of silicon, 30 per cent. of carbon and only 4.78 per cent. of alumina. Experiments then followed with mixtures of carbon, silica sand and salt as a flux, and large crystalline masses of the new product were obtained. Its hardness suggested its use as an abrasive, since it is nearly as hard as the diamond, and its commercial manufacture as a substitute for emery and corundum soon followed.

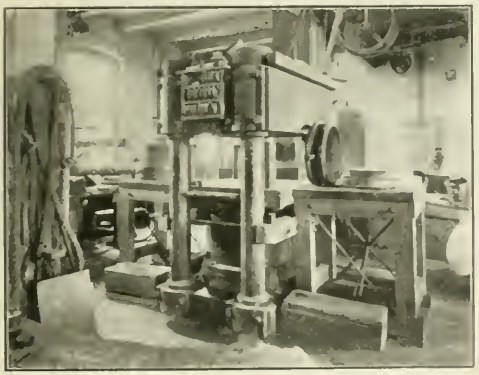
The furnaces employed at Niagara Falls are horizontal, and take 1,000 horse-power each. There are two blocks of five furnaces each, of which one furnace in each block is in operation, while the other four are either cooling off, being emptied

or being loaded up for a fresh run. The bed of fire brick is 16 feet long, 5 feet wide and stands 2 feet above the floor. The ends are of solid brickwork, 2 feet thick and 8 feet high, in the center of which are square iron frames, in which are drilled holes. Through these holes the strands of the conducting copper wires pass, and are connected to the terminal carbons, bunched together, which lead the current into the furnace. Directly in contact with these carbons is placed the conducting carbon core, which conducts the current through the furnace

CARBORUNDUM.

and by its resistance raises the temperature sufficiently to reduce the carborundum-making mixture which surrounds it. When charging is completed, the carbon core is surrounded on all sides by the mixture to a distance of 2 to 3 feet, and the top is rounded off like a mound. The electrical connections are now made to the iron frames, at the extreme ends of the furnace, and the charge is ready to burn.

The alternating current of 250 volts is passed into a 830 kilo-watt (1,100 horse-power) stationary transformer, which



A CARBORUNDUM PRESS.

cuts its voltage down to an average of 185 volts. A regulator allows the current to vary from 100 volts up to 250, while the ampères vary from 2,000 up to 8,000. The 4 per cent. loss in transformation, representing 40 horse-power, would heat up the transformer, but is counteracted by cooling it by circulating currents of oil.

The furnace starts at high voltage and low amperage, because of the poor conductivity of the carbon core when cold. The total contents of the furnace are about 1,000 pounds of carbon core, and the mixture reduced represents 3.5 tons of carbon mixed with 6 tons of silica sand and 1.5 tons of salt, producing in a thirty-six hour run between 3 and 4 tons of commercial carborundum, in crystals, outside of which is a quantity of light-green amorphous carborundum, fully reduced, but uncrystallized, and outside of this the unchanged mixture. Near the carbon core, where the heating is most intense, are found some crystals of carborundum from which the intense heat has volatilized the silicon, leaving a skeleton crystal of graphite, while the silicon, passing outward as vapor, oxidizes to spongy, felt-like silica as soon as it meets carbonic oxide gas. Some of the vapor has been found condensed to metallic silicon in cracks in the bed of the furnace. The observation of the formation of graphite by the very evident decomposition of the silicon carbide, was the starting point of the graphite industry now conducted by Mr. Acheson in an adjacent plant.

A third block of furnaces is now in course of construction, which will raise the power requirement to 3,000 horse-power,

A CARBORUNDUM KILN.

and increase the output of carborundum to 1,800 tons per annum.

The furnace after a run, is allowed to cool several hours, then gradually uncovered, the unreduced mixture removed, the reduced, but uncrystallized, carborundum is put aside to be mixed with another charge, and five to fifteen inches of well-crystallized carborundum next to the heating core is carefully gathered up. The carbon core serves only as a heating agent; very little of the current during reduction passes through the mixed carbon mixture, which is in reality a very poor conductor of electricity. The process is, therefore, simply that of heating the mixture to be reduced by the heat generated in a carbon conductor, which carries the current and which is surrounded by the mixture. The electric current not only heats up the immense mass of charge, but also supplies the heat absorbed in the chemical reactions involved. A consideration of the power used and the products obtained in one run, leads to the conclusion that about 25 per cent. of the energy of the current is needed to heat the materials up to the

reaching temperature, 50 per cent. in supplying the great quantity of heat absorbed in the chemical process of reduction and only some 25 per cent. is lost by radiation during the run (the 25 per cent. first spoken of is lost by radiation after the run has ended).

The cost of power alone amounts to 1.25 cents per pound of crystals obtained, the cost of materials for the mixture 0.75 cent and labor probably another 0.5 cent, making the estimated cost of crude crystals 2.5 cents per pound. This material must be otherwise treated before being ready for market. This subsequent treatment consists in crushing the masses to coarse powder, allowing this to stand several days in dilute sulphuric acid, to remove any such impurities as iron oxide, then washing and grading. The final cost of the powder or grains may be 4 to 5 cents per pound. It is sold at an average of 9 cents per pound; the manufacture of 2,400,000 pounds yearly providing, therefore, an estimated profit of $100,000 to the company. A large part of the product is, however, worked up by the company themselves into wheels, hones, etc., of all sizes and descriptions, the manufacture of which occupies, with its presses, baking ovens, kilns and stock rooms, the greater part of the floor space in the company's factory. This manufacture is an additional and large source of profit.

The crystals are graded in 20 sizes, from No. 8, passing

INTERNATIONAL ACHESON GRAPHITE CO.

through 8 meshes to the linear inch, to No. 220, passing through 220 meshes to the linear inch. The washings from the finest crystals pass into settling tanks, producing so-called *carborundum flour* of three grades of fineness, F, FF and FFF. The finest powders are made by stirring fine powder or flour in water, letting it settle a definite time, one, four, six, ten or fifteen minutes, decanting the liquid and then settling the powder from this by long standing. Such powders are called *hand-washed* one, four, etc., minute powders.

The factory buildings are two and three stories high, covering three sides of a four-acre plot of ground, and contain 120,000 feet of floor space. They contain costly machinery, presses, drills, etc., for making the carborundum up into wheels, sticks, hones, sharpening stones, cloth, paper, etc. The greater part of these goods are made up with a bond of kaolin and feld-spar, which becomes vitrified in the subsequent kiln burning, producing the firmest "body" which can be made.

A particular use to which carborundum has been put is the addition to steel, to secure sound castings, it being thus possible to introduce silicon without bringing a trace of phosphorus or sulphur into the steel. Since the carborundum contains 70 per cent. of silicon to 30 per cent. of carbon, it is very efficient for this purpose.

Immediately in front of the factory is the new office, built in colonial style after designs of Mr. Haskell, president of the company, and one of the prettiest office buildings in Niagara.

### The International Acheson Graphite Co.

Manufactured graphite was suggested as a commercial possibility to Mr. Acheson by finding in the center of his carborundum furnaces masses of graphite resulting from the overheating of carborundum. The making of carborundum is a delicate operation, the proper adjustment of current to core being absolutely necessary for producing a good output. It has been stated that an increase of 3 per cent. in the size of the conducting core, in a carborundum furnace will result in a great decrease in the amount of carborundum formed, because of deficient temperature, while an increase of 3 per cent. above the normal will result in the conversion of considerable carborundum into graphite, by volatilization of its silicon. In other words, the temperatures of formation and of decomposition of carborundum lie somewhat close together, probably not over 500° Centigrade apart.

Having thus an idea of a new principle which was available for producing graphite, Mr. Acheson experimented further, with the result of becoming convinced that all metallic carbides, on being decomposed by heat, leave behind graphite, and his patents and process are based upon that fact.

The company concerned was organized in 1899, with Mr. Acheson, president; A. W. Mellon, Pittsburg, vice-president, and P. McN. Bennie, secretary. The patents by which they work are U. S. Patent 542,982, of July 23, 1895, which relates to the production of pure electric-light carbon by subjecting impure carbon to a high temperature for a sufficient length of time to volatilize its impurities; U. S. Patent 568,323, of September 29, 1896, and 617,979, of January 17, 1899, which disclose the principle of converting carbon into graphite by mixing it with such metallic oxides as would be capable of forming metallic carbides, to be subsequently decomposed; U. S. Patent 645,285, of March 13, 1900, which claims the use for conversion into graphite of such natural carbonaceous materials as contain uniformly intermixed through them metallic oxides sufficient to produce carbides and thence graphite. These patents, taken together, not only form the basis of the commercial manufacture of graphite, but throw much light on the scientific question as to the manner of its formation.

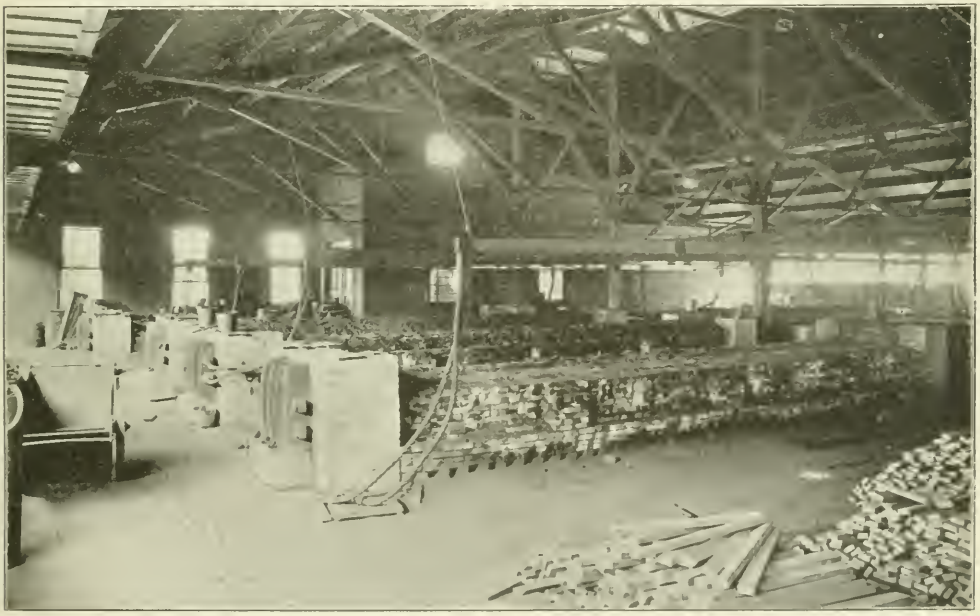
The furnace building is of brick and iron, 100 x 50 feet, and contains two rows of five furnaces each. Back of this is a frame building with machinery for grinding coke and coal, and making the furnace mixtures. The power used is 1,000 horse-power, converted down from 2,250 volts to an average of 150. The blocks are run very much like carborundum furnaces, in that while one furnace is being run, the four others are in various stages of dismantlement or re-filling. The commercial work of the company has resolved itself into two lines of manufacture: (1) the graphitization of molded carbons, (2) the graphitization of anthracite coal *en masse*. The product is, in either case, pure graphite, which should be known as *manufactured* graphite rather than *artificial* graphite, since it is no counterfeit of graphite, but the real graphitic carbon itself. A good summary of the history of the invention, by Mr. Acheson himself, may be found in the *Journal of the Franklin Institute*, for June, 1899, and a discussion of the value of the resulting product, by Mr. Collins, in the *Transactions of the American Electrochemical Society*, Vol. I, 1902.

The conversion of molded carbon articles into graphite is performed by stacking them transversely to the current in a pile about 2 feet square, between terminals 30 feet apart, and covering them thickly with fine granular carbon and carborundum. A quite recent patent to Mr. Acheson (U. S. Patent 702,758, of June 17, 1902), has for its subject-matter the particular manner of stacking such articles for graphitization, the granular carbon between the articles being the principal heat-producing agent, while the heat generated in the articles themselves is of secondary value because of the transverse position of the articles. By this arrangement the furnace charge offers such resistance to the current that it may

be held at a very high temperature, while the conducting terminals, of solid carbon, but of much smaller cross section than the furnace charge, are at only a moderate temperature. (This is also discussed by Townsend in the *Electrical World*, of June 28, 1902.) The current is then put onto the furnace, at 220 volts and 3,000 amperes to start with, and gradually increasing to 80 volts and 9,000 amperes at the end of a twenty-hour run. At the close of the run the furnace is allowed to cool off several hours before uncovering. The heat is thus sufficient to graphitize the furnace charge completely and also even some of the outer packing of granular carborundum. If the articles have not been heated sufficiently, they will still contain some amorphous carbon, which will dissolve in acids and alkaline solutions, and disintegrate the article; if they are overheated they may become too dense and develop cracks on cooling or subsequent use. Many hundred thousand of carbon electrodes, 15 inches long by 1 inch cross section, used in the liquid caustic alkali process, have been made in this way, and have given such satisfactory service that Mr. Acheson's business has really suffered by the surprising long life (one to two years) of these electrodes and the consequent paucity of renewals. Blocks, 8 inches by 10 inches and 4 inches thick, as well as rods, 4 inches square by 24 inches long, have been perfectly graphitized in these furnaces.

Since three to three and a half tons of material can be graphitized in one charge, with nearly an equal amount of granular carbon and carborundum on the furnace, we can calculate, from a consideration of the current used, that it would take the current used over sixteen hours to bring the furnace up to the volatilizing point of carbon, which is not far above the temperature of graphitization. The current being run for twenty-four hours, it follows that just about one third of the total heat energy of the current is radiated or conducted away during the run, while two-thirds are represented by the heat in the hot furnace at the end of the run, the heat in the actual articles being graphitized being 40 per cent. of the heat energy of the current. The conversion of amorphous carbon into graphite is, of itself, a heat-evolving reaction, such that the graphitization of 7,000 pounds of carbon would represent 7,000 × 230.5 = 1,655,500 pound-calories (1° C.) or some 5.7 per cent. of the energy which the current furnishes, but against this can be set the heat necessary to reduce metallic oxides and dissociate carbides, which will be a factor of about the same value.

As to the articles thus graphitized, they possess a specific resistance of but 0.00032 ohm per cubic inch, which is but one-fourth that of amorphous carbon. (This specific resistance is 0.0008 ohm per cubic centimeter, and since that of mercury is 0.0000094 ohm, the conductivity is 1175, mercury being 100, or 0.21, copper being 100). As for durability, such carbons have been used as anodes in alkaline chloride solutions for three years, with a current density of 50 to 250 amperes per square meter, without as much as rounding off the sharp edges. In electric-furnace work, at high temperatures, the consumption by oxidation is one-fourth, or less, that of



GRAPHITE FURNACES, ACHESON GRAPHITE CO.

amorphous carbons under similar circumstances, making their use in many cases very advantageous.

The other line which the electrical manufacture of graphite has taken, is the conversion of carbon in bulk into graphite. For this purpose some carboniferous material is taken which has a considerable quantity of ash, or metallic oxide impurities, uniformly distributed through it. The purest carbon, such as petroleum coke, which contains only 0.3 per cent. of ash, graphitizes very poorly; similarly, ordinary coke will graphitize completely only where the ash is uniformly distributed, but those parts of the coke which have been formed from the baking of exuded pure bituminous matter are too pure to graphitize and yield a poorly-converted product. Clean anthracite coal, such as washed *pea* or *buckwheat* coal are the best adapted, and give very satisfactory results, for in them nature has distributed 5 to 15 per cent. of ash with almost molecular uniformity.

The furnace for this conversion is 30 feet long and is formed of a trough 2 feet square, lined on bottom and sides with blocks

of compact carborundum 6 inches thick. This is found to be a very satisfactory lining for high-temperature electric furnaces, to build walls in places where the best fire brick would melt too easily and carbon bricks would be subject to oxidation. The coal is ground to about the size of rice and the furnace trough first half filled. Graphite rods are inserted in the ends, to conduct the current into the mass, and a core of granular carbon, partly graphitized, about 6 inches wide, is laid from one end to the other, in order to start the current, since cold anthracite is of itself so poor a conductor that, otherwise, it might be impossible to start the current flowing with the maximum volts at command. The furnace is then filled up, and a layer of coarse carbon and granular carborundum placed on the top. The charge of anthracite is about six tons, and it is graphitized in twenty hours. A consideration of the energy of the current and the amount of material treated lead to the conclusion that about 82.5 per cent. of its energy is consumed in raising the charge to the graphitizing temperature and 17.5 per cent. radiated during the run; or, stating it another way, it requires theoretically sixteen hours and thirty minutes' running to bring the whole charge up to the graphitizing temperature, and the rest of the twenty hours is used in keeping it there and supplying radiation. The heat *evolved* in conversion of amorphous carbon into graphite amounts in this case to fully 10 per cent. of the heat supplied by the current, but this is just about balanced by the heat absorbed in volatilizing the 5 to 10 per cent. of impurities from the coal.

The amount of unconverted amorphous carbon is most easily estimated in the laboratory by attacking it with concentrated nitric acid at 86° C., when the brown coloration of the liquid gives the means of estimating the amorphous carbon present. Natural graphite contains some amorphous carbon, say 0.1 to 0.2 per cent.; the manufactured graphite from anthracite coal may contain up to 2 per cent., the graphitized articles to which have been added iron oxide to facilitate conversion, contain often as little as the native graphite.

Many kinds of graphite may be produced from different carbonaceous materials treated in different ways and crushed afterwards in different manners. There is the soft and the dense, the laminated, foliated and stratified kinds, the fibrous, like Ceylon *wood* graphite and the scaly, like Ticonderoga graphite. Different kinds are suitable for different purposes; the scaly for crucibles and lubricating purposes, the dense for hard lead pencils, the soft for foundry facings, stove polishes and iron-protecting paints. The total yearly production of this factory is nearly 1,000,000 pounds, at an average value of 8 cents per pound; graphitized electrodes are valued at 12 to 15 cents per pound and graphite in bulk from 10 down to 4 cents, according to purity and flakiness, and the product represents a considerable fraction, some 20 per cent. of all the graphite produced in America.

### The Acker Process Co.

The projectors of this company are the brothers C. E. Acker and A. E. Acker, who began in 1894 experimenting at the problem of electrolyzing melted sodium chloride, and producing thereby caustic soda and chlorine. An extensive description of the process which has been evolved, written by C. E. Acker, is in the *Transactions of the American Electrochemical Society*, Vol. I, 1902. The patents under which the company work are U. S. Patents 649,565, of May 15, 1900; 674,691, of May 21, 1901, and 687,709, of December 3, 1901, to Chas. E. Acker.

The plant established at Niagara Falls is situated 1,500 feet below the lower power house, on a 10-acre piece of ground, and comprises a large reduction room, some 80 by 150 feet in plan, a still larger building of brick and iron for the bleaching powder plant, besides an extensive machine shop, brass-casting foundry, pattern shop and large offices. Some 250 men are in the company's employ.

The idea of Acker's process, and elaborated in his patents, is the electrolyzing of melted sodium chloride resting upon melted lead, the latter serving as cathode. The lead-sodium alloy is then decomposed by a jet of steam in another part of the same apparatus, producing melted caustic soda, which flows away and hydrogen which immediately burns. The process is carried on in a heavy cast-iron vessel, 5 feet long, 2 feet broad, with a bowl about 12 inches deep. The sides, above the surface of the melted lead lying on the bottom, are protected by a lining of magnesia blocks. At one end is a small compartment separated by a partition dipping below the level of the lead, into which the lead alone can pass and in which

ACKER PROCESS CO.

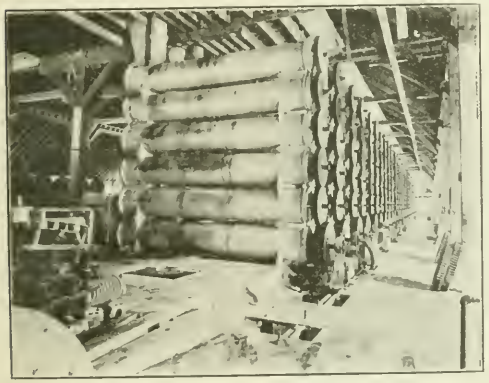
it meets a jet of steam blown directly into it, which oxidizes the sodium to caustic. On top of the lead a bath of sodium chloride is melted, about 6 inches deep, into which dip four graphitized carbon blocks serving as anodes. The lower surface of these blocks are 14 inches long by 7½ inches wide, and reach to within ¾ inch of the melted lead. The blocks are 3 inches thick and are kept in place by heavy 5-inch round graphitized carbons, 12 inches long, two of which are screwed into each carbon block. The upper end of these rods are encased in fire-brick tiles, which, when in place, form part of the cover of the furnace, and electrical connection is made by

ACKER PROCESS CO.

means of heavy brass rods, 1½ inches in diameter, tapped into them, and connecting further up with copper rods, which are held by clamps to the bus bar above. The 5-inch rods are protected by fire-clay sleeves, joints are plastered over with cement. The top of the furnace is further loosely closed by fire-clay slabs, but the joints need not be very tight, since the chlorine is drawn away by side flues by a strong exhaust, making the escape of chlorine into the room impossible. The

salt to be used for charging comes through a hopper from the floor above, and is piled between the furnaces and on part of the cover, so as to become dry and warm before being charged.

The pot room has place for 54 furnaces, in four rows, of which 40 to 45 are in action while the others are undergoing repairs. The current of 3,000 horse-power is sent 1,500 feet from the generating station as direct current of 8,200 ampères, reaching the works at a potential of 275 volts, the cables in the conduit being half the way copper and half aluminum. The pots are all run in one series, so that the drop of voltage is between 6 and 7 volts per pot. The four electrode blocks carry, therefore, about 2,100 ampères of current each, which gives a current density at the lower surface of approximately 2,750 ampères per square foot. This keeps the temperature of the bath at 850° C., a cherry red, which is 75° above the melting point of the salt. The object in conducting the process is to keep as nearly as practicable to the melting point of the salt, in order to avoid the re-solution of sodium and the re-combination which takes place at higher temperatures. The melted salt looks slightly syrupy, and has a silky sheen like melted metal. The workmen regulate the temperature by raising or lowering the electrodes and by charging fresh salt as



BLEACHING POWDER CYLINDERS, ACKER PROCESS CO.

the level of the bath sinks, and they have frequently to break with a bar the crust which solidifies between the carbon rods. The salt is from the neighboring New York salt beds, costs $3 per ton and is not purified before use. The bus bars, for carrying the current, are of copper, and of 9 square inches section, giving 900 ampères per square inch, which is very ample carrying capacity, since aluminum conductors, with only two thirds the conductivity, are sometimes loaded quite as heavily

The steam jet, in the compartment at the end of the pot, is introduced beneath the surface of the lead, but pointing vertically upwards. The jet strikes a curved hood, which brings the material down into a third compartment, about 6 inches by 10 inches in area, in which the lead and caustic separate, the latter flowing out of the furnace over a cast-iron lip, the lead sinking and passing back into the reduction compartment of the furnace, while the hydrogen evolved issues from the spout, burns and is conducted away by a 6-inch sheet-iron pipe to a chimney. The melted caustic runs into a sheet iron pan, where it sets, and is removed every hour. The average output of a furnace is a 25-pound cake hourly. The theoretical amount of caustic which the current should produce being 26.9 pounds per hour, in each pot, the average efficiency obtained is thus seen to be 93 per cent. The voltage used, however, is the other factor of the process which needs considering. There is required, theoretically, 4.2 volts to decompose sodium chloride into sodium and chlorine, but since the sodium unites with lead with great avidity, it is probable that the production of the alloy requires 3.5 volts. Since 6 to 7 volts are used per furnace, we have an average of 3 volts converted into heat. Of this heat evolved, calculation shows that one-sixth is utilized in melting the fresh salt added, while five-sixths is lost by radiation and conduction, and resistance of conductors and connections. Or, considering the whole energy of the current, we may say that 54 per cent. of it is utilized in the chemical reaction, 7 per cent. in melting the salt added and 39 per cent. is lost by radiation and conduction.

The cakes of solidified caustic are taken out of the pans and slide down a chute directly into the cast-iron melting pots, 8 feet in diameter. Here it is melted, allowed to stand six hours to settle and bailed out into sheet-iron drums, 2 feet in diameter by 4 feet high, holding 750 pounds each. The total product is 23,000 pounds of caustic per day.

The chlorine gas is drawn by a powerful fan, 15 feet in diameter, motor driven, through a series of 30 Hassenclever absorption apparatus, each consisting of six drums above each other, 2 feet in diameter by 20 feet long, in which screens revolve slowly in alternate directions. The 50 pounds of slaked lime fed per hour into the upper cylinder is gradually passed by the screw motion from one cylinder to the other, until in twenty four hours it arrives at the discharge hopper, while the chlorine gas, mixed with air, passes in the opposite direction through the apparatus and into a scrubbing tower beyond, where the last traces of chlorine are removed. The total plant takes care of 21,000 pounds of chlorine daily, requiring 36,000 pounds of slaked lime and producing 57,000 pounds of bleaching powder.

With salt costing $3 per ton and power $15 per horse-power per year, the cost of raw material for making a ton of caustic soda is $4.50, the cost of power $11, steam and remelting 50 cents, labor and repairs probably $14 or an estimated total of $40, which is to be diminished by the value of the chlorine for making bleaching powder. Every $1 per ton profit made on the sale of the bleaching powder would mean $2.50 per ton reduction on the net cost of the caustic. Compared with the aqueous processes, Acker's process consumes more power and costs more in replacement of apparatus, but takes less expensive plant and apparatus, and dispenses with the boiling down of the caustic solutions.

We wish success to the manufacturers in both lines

## STATISTICAL.

In a circular, issued by the authorities of the Universal Exposition to be held in St. Louis in 1904—Prof. W. E. Goldsborough being the chief of the Department of Electricity—the following statistical data are given:

Number of electroplating establishments, 500.

Capital invested in electric mining and power transmission properties, $200,000,000.

Capital invested in electroplating and depositions, $50,000,000.

Capital invested in "automobile and electric storage batteries," $25,000,000.

Total amount invested in electrical industries, $3,975,000,000.

Electrolytic production of copper, 200,000 tons per year

Electrolytic production of gold, 170,000 ounces per year

Electrolytic production of silver, 12,000,000 ounces per year

It is not stated whether these figures refer to the United States alone, or to the whole world. But from the figures given for the electrolytic production of copper, it is evident that the United States alone is meant. The figure for the electrolytic production of silver does not seem to be correct, as in the latest volume of *Mineral Industry* (Vol X, page 228) the estimated daily output of three electrolytic silver refineries, in operation in the United States in 1901, is given to be 125,000 ounces Troy. If one assumes only 300 working days per year, the yearly amount of electrolytically-refined silver comes out as 37,500,000 ounces, *i. e.*, more than three times the amount stated in the pamphlet.

## PIONEERS OF ELECTROCHEMISTRY—II.

Alfred H. Cowles.

Alfred Hutchinson Cowles, second son of the late Edwin Cowles, founder and editor, until his death, of the Cleveland *Leader*, was born in Cleveland, Ohio, in December, 1858. His mother, Elizabeth Hutchinson Cowles, fully shared her distinguished husband's appreciation of education, and Alfred Cowles, like his brothers and sisters, was given large opportunities to follow his bent for study. He attended the public schools of his native city, and later he spent two years at the Ohio State University, at Columbus, making chemistry and metallurgy his special studies. From this institution he went to Cornell University, and remained there four years, continuing to devote himself to science.

At Cornell Alfred Cowles became active in rowing, being the captain of the 'varsity crew in his senior year, and going with it to Europe, where the Cornell oarsmen raced at Henley, for the famous Stewards' Challenge Cup, at Putney and on the Danube. But chemistry, metallurgy and physics remained the chief interest of his life, as they have been to the present date.

Alfred H. Cowles

After leaving college, Mr. Cowles spent some time in New Mexico, in the development of mining property owned by his father. When hardly more than a boy he invented an improved backing, still in general use, for matrices in newspaper and other stereotyping. Then, as at all times since, science and invention left room for the general interests of a man of affairs, largely interested in a great newspaper and accustomed from childhood to the consideration of public questions and important concerns of many kinds.

But the chief pursuit and interest of seventeen years for Mr. Cowles has been the electric smelting of aluminum and the researches and discoveries in electrochemistry and physics which have attended and grown out of that central subject of study and experiment. In connection with Eugene H. Cowles, an older brother, the subject of this sketch revealed and developed the great possibilities of the electric furnace, especially in the production of aluminum and alloys of that metal. The Cowles Electric Smelting and Aluminum Co. were organized and works were built in 1885 at Lockport, N. Y., where extensive water-power could be obtained. By means of the electric furnace, first used commercially by Alfred and Eugene Cowles, and brought by them before the world of science, as well as business, alumina and many other minerals, some of them rare and refractory, were disrupted for the first time by any other than a chemical laboratory process.

Patents were taken out in Great Britain, Germany and other foreign countries, and a company were organized in England to produce aluminum and its alloys.

Between 1885 and 1890 the Cowles Co. offered aluminum, for the first time anywhere in the world, in cheap form and commercial quantities, although almost wholly in alloys, especially bronze.

Out of this business sprung many important discoveries in electrochemical smelting. Among the results are calcium carbide, which is said to have been produced, in a small way, in the Cowles electric furnace while it was used in Cleveland. Thomas L. Willson, who was then employed in the Brush Electric Works in that city, later developed the production of calcium carbide on a commercial scale at Spray, N. C., and from this source, since greatly enlarged and improved, has come the supply of acetylene gas for various purposes.

Carbon bisulphide is now made on a large scale at Penn Yan, N. Y., by Chas. B. Taylor, formerly of Cleveland, by the adaptation of the electric furnace to an industry which depended, until that furnace came into use, on chemical means of production. At Niagara Falls phosphorus is produced by a process which is said to be an outgrowth of the Cowles discoveries. It is the direct result of the researches and inventions of Dr. Redman, employed at the works of the British "Cowles Syndicate" when that company were located at Stoke-on-Trent.

Another notable development from the electric furnace has been the carborundum industry, now attaining large proportions at Niagara Falls. In 1890 Edward G. Acheson, a young student and experimenter from the laboratory of Thomas A. Edison, undertook, by the use of the electric furnace, to make diamonds. He produced hard, lustrous crystals, composed of carbide of silicon, and found them commercially available as a substitute for emery and other abrasives. From this beginning an important business has developed, but it is said that the foundation for it was laid in 1884, when Alfred Cowles and his brother, now many years deceased, are said to have first produced carborundum in their electric furnace in Cleveland.

In the early days of the Cowles Electric Smelting and Aluminum Co. their experiments and improvements did important pioneer work for the United States and for other countries in the use of large dynamos.

The development of the aluminum industry by the Cowles Co. has been much impeded by prolonged and costly litigation, begun in 1891, over certain fundamental patents. Four great cases have been contested in the United States courts, and two have been carried to a final decision in favor of the Cowles interests. The others are awaiting a hearing in the Circuit Court of Appeals, after decisions adverse to the Cowles side in the lower courts.

The work of Cowles has resulted in the production of many articles in common use, from the lamps on bicycles to aluminum for the transmission of electric energy.

Alfred H. Cowles is still active and fertile in scientific research, and his studies run into fields of investigation and discovery widely different from that which has been the main interest of his life.

# NIAGARA FALLS MEETING
OF THE
# AMERICAN ELECTROCHEMICAL SOCIETY.

THE second general meeting of the American Electrochemical Society, held at Niagara Falls, N. Y., from September 15th to 18th, turned out to be a splendid success in every respect. The actual attendance at several of the meetings was nearly 200, while the number of members and guests registered was 164, an alphabetical list of the latter being given on another page of this issue.

The local committee, comprising the Niagara Falls members of the Society, with Chas. M. Hall as chairman, and a ladies' committee, with Mrs. Chas. E. Acker as chairman, had arranged an extensive programme for the different days of the meeting, and did everything in their power to make the visitors feel at home. A search-light trip over the Niagara Gorge trolley line to Kingston and back, on the evening of September 16th, was especially enjoyable. On the evening of September 17th the local committee gave an elaborate banquet to the members and guests of the Society at the International Hotel. This was followed by dancing in the hotel parlors. Wm. B. Rankine, who presided as toastmaster at the banquet, responded to the toast "Niagara Falls;" President J. W. Richards to the toast to the Society; Prof. Haber spoke for the German Bunsen Society and R. S. Hutton for the electrochemists in Great Britain; Prof. W. D. Bancroft responded to the toast "Our Universities;" Prof. F. B. Crocker to a toast on the sister societies, and Dr. N. S. Keith to a toast on the ladies. The banquet was attended by 150 persons.

Some disappointment was being felt on account of the fact that the managers of most of the electrochemical plants of Niagara had previously decided to keep up their old policy of secretiveness, and not to open the doors of their workshops to the members of the Society. Only four electrochemical works made an exception, and their courteous invitation was greatly enjoyed. They were the International Acheson Graphite Co., the Carborundum Co., the Electrical Lead Reduction Co. and the Atmospheric Products Co. The same courtesy was extended by the Niagara Power Co., the Hydraulic Power and Mfg. Co. and the Natural Food Co. The visits to these plants were very enjoyable, and while they represented only a small percentage of all the plants, it is perfectly true that on the whole the members of the Society saw more in Niagara than they can ever see at any other single place in the United States.

From official statements given out at the meeting, it appears that the financial conditions of the Society are in a fairly good shape. The number of members, including the applicants to be elected at the next meeting of the Board of Directors, is 433. The New York members, through A. von Isakovics and Dr. N. S. Keith, extended a courteous invitation to the Society to hold the next meeting in New York City, in the spring of 1903. This meeting will be the annual business meeting, while the Niagara convention was devoted entirely to scientific and technical matters. Technical sessions were held on every morning of the four days the convention lasted, and, in addition, in order to get through the whole programme of papers, it became necessary to hold a session on the afternoon of September 17th. In the following we give a concise review of the proceedings:

## MONDAY'S SESSION.

The first paper presented to the Society was by Francis A. J Fitzgerald, on "Testing Carbon Electrodes." He discussed methods used by the Acheson Co. for determining the density of a carbon electrode and for determining the amount of amorphous carbon in a graphite electrode. A long abstract of this interesting paper is given on another page of this issue. The paper was discussed by Messrs. Hart, Hutton and Keith. Professor Hart suggested the use of persulphates for distinguishing between amorphous carbon and graphite in a similar way as they are now used in the determination of manganese in steel. Mr. Hutton called attention to the different behavior of graphite made in different ways, principally by dissolving the carbon in different metals. This was confirmed by Mr. Fitzgerald, who said that there are as many kinds of graphites as there are of amorphous carbon, and that the subject is really a very vast one.

The next paper was read by Dr. J. W. Richards, on "The Efficiency of Electric Furnace Operations." A longer abstract of this paper is given on another page of this issue. The paper was discussed by Messrs. Hering, Bancroft, Hart, Whitney and Haber. Mr. Hering pointed out that the determination of the efficiency requires the knowledge of the theoretical amount of energy necessary for a given process, and that this theoretical amount is often not definitely known. For instance, in the case of calcium carbide, the theoretical values given by different authors vary greatly. In reply to a question on the possibility of reducing the radiation loss by getting up the walls of the furnace in such a way as to leave small air chambers throughout the wall, Professor Richards replied that he thinks it is better to relatively reduce the radiation loss by increasing the size of the furnace and working at a faster rate.

The next paper on the programme, by P. G. Salom, on some improvements of the process of electrical lead reduction, was not read, on account of pending patents. It was promised for the next meeting. The theoretical problems involved in this process were, however, discussed at length in an interesting paper presented by A. J. Weightman, on "Cathodic Reduction." A longer abstract of this paper is given on another page of this issue. It elicited an animated discussion, in which Messrs. Reed, Keith, Hering, Rodman, Haber, Hutton and Blackmore participated. Mr. Reed did not think that it is necessary to have recourse to Caspari's theory of the overvoltage. He claimed that Weightman's results could be explained by the simple rule that where there is a mixture of cathodes (*i. e.*, where the cathode contains two materials capable of reduction) the current divides itself between the two in a proportion depending upon the accessibility of these two cathodes. On the other hand, Professor Haber held that such considerations do not overcome the difficulty, that hydrogen will not develop on the cathode without overvoltage. He suggested that there might be intermediate steps between the formation of gases from ions, such as solution, adsorption, the formation of an alloy, etc.

The last paper of this session was read by Dr. Louis Kahlenberg, on "Differences of Potential between Metallic Cadmium and Solutions of Cadmium Iodide in Various Solvents." Cadmium iodide was used as the solvent, because it is readily obtained in a pure anhydrous form, and is soluble in a goodly number of solvents, the resulting solutions often being fair electrolytes. As solvents, mostly nitrites and amines were used. The concentration used was 0.1 gram equivalent per liter, or concentrated solutions were used in case the salt was not sufficiently soluble. The difference of potential between metallic cadmium and the solutions of cadmium iodide was measured against Ostwald's normal electrode (a normal solution of potassium chloride in contact with an excess of mercurous chloride and metallic mercury). The cadmium was always the negative pole. The e. m. f. of the normal electrode was assumed to be — 0.56 volts, and the e. m. f. at the junction of the two liquids was neglected. The principal result of his measurements may be stated as follows: The difference of potential between a metal and a solution is

determined by the chemical affinity between the metal and the solution. Differences of potential between a metal and a solution of the same strength in solvents that are chemically very different are of the same general order of magnitude, though they are by no means identical.

Before this session was closed, Dr. C. A. Doremus called attention to the International Congress for Applied Chemistry, to be held next June, in Berlin, under the auspices of the German Government. Dr. Wiley, of the United States Department of Agriculture, forms a committee of organization for America. An important section of the congress will be the electrochemical section. He moved to request the Board of Managers to take action regarding the appointment of delegates to this congress. The motion was carried.

During the afternoon the visits to the various plants, mentioned above, took place.

## TUESDAY'S SESSION.

The first paper of this session was by Marcus Ruthenberg, on "Developments in the Electrometallurgy of Iron and Steel." In the absence of the author it was read by Dr. E. Hart. A longer abstract of this paper will be published in our next issue. It was discussed at length by Messrs. Hart, Keith, Johnson, Hering, Reed, Salom and Richards. Dr. Hart mentioned a process by Blake of electric (not magnetic) concentration, used in an experimental plant of Schwartze, in Denver. The small particles of ore are charged electrostatically. Some of the particles take the charge more rapidly than others and lose it less rapidly. This gives a new principle of separation, the quantity of energy required being quite small. Moreover, it is possible to separate, in this way, particles which cannot be separated very easily by water concentration, because of their fineness. He thought that Mr. Ruthenberg takes too sanguine a view of the possibilities of the electric furnace in iron smelting, as it should not be forgotten that to-day the iron-smelting furnace is absolutely the most economical furnace in existence. Other speakers also expressed the opinion that the electric furnace for iron and steel has the very great handicap of high cost. Dr. Keith referred to Edison's efforts in magnetic separation. Mr. Reed remarked that Edison's problem is a very difficult one, as he starts with an ore which contains on an average about 20 per cent. of iron; the rest is rock, and there is also a large amount of phosphorus. The ore must first be ground to a very fine mesh; then the phosphorus is removed; then follows washing, drying and briquetting before the ore can be concentrated in the magnetic separator. These various processes make the product quite expensive. Mr. Reed believed, however, that magnetic separation is quite economic for certain kinds of ore, which exist in immense quantities, and have only to be ground to a quarter or one-eighth mesh, and then merely have to be run through a magnetic separator, without requiring further treatment. Mr. Salom expressed the opinion that there is not much danger in the immediate future of the electric furnace superseding the blast furnace as a method of manufacturing iron or steel, although the possibilities of it are not to be ignored in the future. He also thinks that, in view of the enormous amounts of high-grade ores that are still in existence, all the attempts at concentration processes will be a failure until the good ores become scarce. It does not pay to operate 5 and 10 per cent. ores when one can get 50 and 60 per cent. ores. Magnetic separation may, however, be economic with ores below 50 per cent., and containing a large amount of phosphorus. It pays to bring them up to over 50 per cent. and get rid of the phosphorus.

The next paper was read by Dr. Eugene A. Byrnes, on "Voltaic Cells with Fused Electrolytes." The author gave the results of a great number of measurements of the e. m. f's of voltaic cells of the type generally called a "carbon cell." The electrolyte used throughout was primarily sodium hydroxide, contained in an iron or other vessel and maintained in fusion by a gas furnace. The electrodes were of carbon, especially graphite, and of various metals. In one set of experiments, both electrodes were introduced into an open vessel containing the molten sodium hydroxide. In the other set of measurements, the molten caustic was divided into separate portions by a porous cup, and various oxidizing agents or depolarizers were supplied to the portion containing the cathode. The porous cup was made by taking two concentric cups of perforated sheet iron, separated by a space of 1 cm., this space being filled with "an oxide" in granular form. Concerning the results of the measurements—which mostly gave e. m. f's much smaller than 1 volt—the reader must be referred to the full paper, which will be published in the "Transactions of the Society." Some of his results are in fair agreement with former results of Liebenow and Strasser. In the discussion of the paper Mr. Reed remarked that he believed the e. m. f. of such cells to be mostly thermo-electric. Dr. Byrnes, in his reply, did not deny that there may be a thermo-electric effect, but it is only partial and not the principal effect.

The next paper was read by R. S. Hutton, of Owens College, Manchester, England, on "The Fusion of Quartz in the Electric Furnace," for the purpose of making quartz fibers and small tubes for scientific purposes. A transparent, glass-like substance is produced, which has an exceedingly small coefficient of expansion and a high melting point. In the first attempts of heating quartz in the electric arc, chemical changes were observed, reduction to silicon and carborundum. If precautions are taken, however, to insure an oxidizing atmosphere around the quartz, it can be easily fused by the arc without any complications. He first experimented with a small open arc, with a magnetically-deflected flame, but this method is not suitable for working at a large scale. He later experimented with a small laboratory electric furnace of the Moissan type, using a direct current of 300 to 500 ampères, at about 50 volts. The method used consists essentially in making a mold and casting the tube in this mold. The mold consists of a graphite block, and is grooved out. As an axis, a small graphite rod, of the diameter of the bore of the tube required, is supported on end pieces. The mold is fed gradually under the arc, the portion immediately underneath becoming very quickly fused, when the carbon is advanced little by little, until the whole mass is fused along its entire length. The mass thus produced always contained a large number of small inclosed air bubbles, which greatly impair its transparency. He also tried the following method: A carbon rod, or carbon of any other shape required, is brought to white heat by passing an electric current through it, the carbon being surrounded by sand or finely-divided quartz crystals. In this way, in almost a moment, the heating is sufficient to cause a powerful agglomeration of the particles of silica in the neighborhood of the heated carbon, and although by the process the material only becomes melted just at the inside, near the carbon, he believes such a method would be useful for forming a tube or other shaped masses which can afterwards be treated. Mr. Hutton's paper was discussed by Messrs. Whitney, Bancroft, Fitzgerald and Doremus.

The next paper was read by Prof. Henry S. Carhart, on "A Thermo-electric Theory of Concentration Cells." The paper was an extension of the theoretical considerations given in the author's paper published in Electrochemical Industry last month. The author showed how both Nernst's theory and Helmholtz's formula led to the definition of a concentration cell as a device for converting heat into electrical energy. For the understanding of a concentration cell, it is therefore necessary to study the thermo-electric forces at the two electrodes. He has discovered the law that the thermo-electric force increases with the concentration of the solution. According to his theory, the e. m. f. of a concentration cell is represented by the difference of the two thermo-electric forces at the electrodes, and this difference is not zero, because the thermo e. m. f. at the concentrated solution is greater than at the dilute solution. He exhibited very interesting curves, and made an application of his results to the theory of the Daniell

cell. The paper elicited an animated discussion, in which Messrs. Bancroft, Haber, Hering, Kahlenberg, Carveth, Patterson, Weightman, Reed, Richards and Keith participated. Professor Haber claimed that Helmholtz's formula and Van't Hoff's formula, taken together, explain completely anything concerning the theory of a concentration cell. Mr. Weightman had made some experiments with the nickel cell described by Professor Carhart in a former paper. He short-circuited such a cell, and found that he did not get a deposition of nickel at all in the dilute solution, and that although the electrode in the strong solution lost a certain amount of weight, it did not go into the solution as a sulphate.

The next paper was read by Carl Hering, on "An Apparent Electrochemical Paradox." He described a curious experiment which he and Mr. Reed made some years ago, in which water was decomposed in visible quantities at voltages far below the theoretical value (about 1.45 volt), even as low as about 0.3 volt. This seems to contradict the law of the conservation of energy, as these gases in re-combining could generate more than this amount of energy. The experiment consisted in electrolyzing acidulated water in a strong N-shaped glass tube, which was sealed at both ends and provided with a bend containing mercury, which enabled the mechanical pressures to be read off. The results were shown in a curve. The pressures reached about 23 atmospheres, when the tube exploded. The voltage at the terminals, when a constant current passed, diminished rapidly and very decidedly to about 0.3 volt at about 16 atmospheres, and then remained practically constant. Allowing for the loss due to resistance, the actual voltage of decomposition was even much lower, nearly zero. There was visible gasing during the whole test, showing that water was really being decomposed. The increasing pressures also showed this. No researches were made to find the correct explanation of this curious result, the intention of the paper being merely to describe the experiment. A possible explanation was, however, suggested, showing how the results need not be inconsistent with Faraday's law or the law of the conservation of energy. It is based on the assumption that some of the gases liberated at one electrode probably passed mechanically to the opposite electrode, which they could easily do in suspension, as the electrodes were very close together. These were then consumed as depolarizers, and this depolarization lowered the voltage. The paper concludes with a suggestion of an experiment in which water is electrolyzed in a strong sealed vessel which is completely filled, so as to leave no room for the gases. Some curious results may then be expected. Mr. Hering's paper was discussed at great length by Messrs. Rodman, Johnson, Carhart, Reed, Hutton, Burgess, Bancroft, Kahlenberg, Haber and Richards. Some similar experiments were mentioned, and in general the explanation given by Mr. Hering seemed to be accepted by the speakers.

## WEDNESDAY'S TWO SESSIONS.

The first paper of the morning session was read by Prof. W. E. Goldsborough, on "Electrochemistry at the World's Fair, St. Louis, 1904," a longer abstract of which will be published in our next issue. The paper was a strong plea for co-operation of the Society to make the exposition a great success in the electrochemical department. The aim will be to make the people of the country at large familiar with the applications of electrochemistry. Processes will be shown in operation. He urged manufacturers to exhibit model plants which show the principle of the process in working. They may embody only the fundamental and essential points of the process, and may differ in many details from the actual process as worked on an industrial scale, so that no trade secrets are revealed. The address was heartily applauded, and the following resolution, proposed by Carl Hering, and seconded by Messrs. Carhart and Coho, was then unanimously accepted by the Society:

"Whereas, The American Electrochemical Society, in convention assembled, recognizes the great international importance of the Louisiana Purchase Exposition, and feels that it will do much in placing before the people of the world a true picture of our national progress; and,

"Whereas, In no branch of our scientific or industrial progress have greater developments taken place recently than in the field of electrochemistry;

"*Resolved*, That the American Electrochemical Society hears with great satisfaction the announcement that steps are being taken looking to the organization of a fine and comprehensive exhibit in the group of electrochemistry, and offers assurances of hearty good-will and co-operation in the accomplishment of this much to-be-desired end."

The next paper was read by Dr. H. T. Barnes, on "The Theory and Practice of Continuous Flow Calorimetry." The method discussed in this paper has been worked out with great care in the last five or six years. It is useful for actual calorimetric measurements in the laboratory, and to show the relationship between electrical and heat units. It is to be used in connection with the Weston electrical instruments. In principle the method consists in having a flow of liquid continuously heated by an electric current in a fine flow tube. The liquid is allowed to flow until the temperature conditions have become perfectly steady. The temperatures of the inflow and outflow and the e. m. f. and current are then measured. The method has been elaborated with the greatest accuracy, and is an interesting example of the high accuracy which can be obtained in the experimental methods of modern physics. The author discusses the sources of error, and shows how they are eliminated. To mention only one detail, the heat wire is in the form of a spiral, in order to break up the stream lines in the liquid, which is very important. The paper was discussed by Messrs. Kahlenberg, Cowles, Hutton, Potter, Whitney, Carhart and Patterson. Mr. Potter suggested a somewhat different mechanical construction. Professor Carhart pointed out the great exactness of modern methods of measurements, indicated by the fact that Barnes' measurements lead to results which agree exactly with Carhart's determination of the e. m. f. of the Clark cell.

The next paper was read by Woolsey McA. Johnson, on "The Electrolytic Dissolution of Soluble Metallic Anodes." A longer abstract of the paper, which is an interesting discussion of several points of the theory of electrolytic refining processes, is given on another page of this issue. The paper was discussed by Messrs. Bancroft, Keith and Reed. Dr. Bancroft corrected a mistake in an assumption made by the author, and Dr. Keith claimed that the alleged difficulties in processes of electrolytic refining do not exist in reality.

Arvid Reuterdahl then read a paper on "The Electronic Hypothesis and its Applications." This paper was a continuation of the discussions started by the author in a paper read before the Society at the first meeting, in Philadelphia. Like the former paper, his present paper is rich in sarcastic and amusing remarks on the very artificial assumptions often made by theoretical physicists, in order to save a theory; for instance, the various assumptions concerning the properties of the ether, etc. The author first discusses the phenomena which have led to the hypothesis of electrons. One point to which he called strongly the attention of the hearers was that an electron is assumed to represent not only an electric charge or quantity, but also to have a mass. He claimed that the latter point is often forgotten by theoretical physicists in applying the hypothesis of electrons. In the second part of his paper he spoke at length of the law of gravitation, and attempted to prove that it is too one-sided, because it speaks only of attraction. He wants to substitute for it the electric law of inverse squares and claims that all difficulties then disappear. In the discussion which followed Dr Whitney made some remarks on experimental researches begun by him with the intention to detect positive electrons. Professor Carhart entered a strong protest against at least one of the critical remarks of Mr. Reuterdahl on difficulties of the molecular theory, and said that these difficulties had long ago been satisfactorily explained

by Clausius. Mr. Reuterdahl, in a brief reply, insisted on the position he had taken in his paper.

Hugh Rodman then read a paper on "Storage Battery Invention," which is essentially a critical comparison of the lead cell and the new Edison cell. A longer abstract is given on another page of this issue. The paper was discussed by Mr. Reed, Dr. Keith and others. Dr. Keith expressed the opinion that the inherent difficulties which the Edison is claimed to have are more alleged than real. Mr. Reed said that if certain reports of the daily press concerning actual runs of automobiles with Edison batteries are correct, then the problem has been completely solved by Edison. It appeared, however, that most of the speakers were somewhat skeptical concerning the exactness of those newspaper reports.

In the afternoon session the first speaker was Dr. F. Haber, professor of the Institute of Technology, in Karlsruhe, Germany. As the official delegate of the German Bunsen Society, he brought to the American Electrochemical Society the good wishes and greetings of the German sister society. He then read his paper on "The Phenomenon of the Formation of Metallic Dust from Cathodes." He has studied for several years this phenomenon, which seems singular at first sight, but is of greater general importance. He showed two experiments in which he sent the current from 20 storage batteries through a cell containing a 20 per cent. solution of potassium hydroxide. In both experiments an iron nail was the anode, while the cathode was a nail of lead in the one case and a nail of tin in the other. When the current is closed, a black cloud of dust goes off from the cathode, and is distributed in suspended form throughout the solution, so that it finally looks like ink. The cloud consists of dust of the material of the cathode. This phenomenon takes place when the current density at the cathode is sufficiently great. The explanation of the phenomenon is as follows: The cation of the solution forms an alloy with the metal of the cathode. This alloy contains a relatively high percentage of the alkali metal, if the current density at the cathode is high enough. It can be shown, however, that such an alloy cannot exist in contact with water or a caustic alkali solution. If such an alloy is prepared by a purely chemical method, and is brought in contact with water, exactly the same formation of dust occurs. Hence, in his experiments, the electrochemical action consists in bringing the alkali metal cations to the cathode; they form an alloy with the metal of the cathode, and, by secondary chemical action, this alloy is decomposed and the formation of dust takes place. When the cathodic current density is high, rich alloys are formed, and the formation of dust takes place. When the cathodic current density is low, the alloys will be poorer; there is no formation of metallic dust, but the surface of the cathode shows signs of having been attacked. Similar experiments have been made with lead and bismuth cathodes in acid solutions. An alloy of hydrogen is formed in this case, which is rapidly decomposed in contact with water, and gives off hydrogen.

The paper was discussed at length by Messrs. Keith, Bancroft, Carhart, Kahlenberg, Reed and Richards. Dr. Bancroft suggested that there might be a connection between this phenomenon and the fact that certain cathodes have a greater reducing power than others. Dr. Haber confirmed this, but stated that it is difficult to say exactly what the relation is between the alloy formed and the change of the reducing power. Mr. Reed had previously described the same phenomenon. Professor Carhart described the following method of producing a very firmly-adhering layer of platinum black on platinum: He decomposes zinc sulphate with a very small current, say 0.1 ampère and 50 square centimeters surface of platinum cathode, for five or six hours. Afterwards the circuit is broken and the platinum plate is left in the solution; in some hours it turns black. The explanation is that an alloy of zinc and platinum has been formed, which cannot exist on account of the free acid present in the solution, and is then decomposed. Dr. Kahlenberg remarked that well-adhesive electroplating deposits can only be obtained if first an alloy is formed.

The next paper was read by Alfred H. Cowles, on "Certain Electrical Units," suggested in order to co-ordinate mass quantity with electricity quantity, and for use in tracing energy in its transformations accompanying chemical reactions. The paper was interesting, as it showed some very simple numerical relations which enable the author to suggest a new system of units for practical purposes. The author goes even further; he endeavors to prove that those simple numerical relations are not merely accidental, and he tries to find their deeper unknown significance. This part of the paper is strikingly original, and shows the characteristic qualities of the pioneer who goes ahead and asks: "Why is it?" where others would simply speak of an accidental coincidence, and would not care to look for deeper unknown causes. True, Mr. Cowles has not yet found the last connecting link which would prove that there is really a deeper significance in the relation found by him, yet, as he is convinced that it exists, he is right in speculating to find it, for "if you do not speculate you can never strike the truth."

The author considers units as "measuring tools for use in reasoning," and points out that for special subjects, like electrolysis, they should be of such convenient dimensions as not to be cumbersome. He has found that, as a coincidence, 500 ampères in one day (12,000 amp. hours) decompose practically (within 1 per cent.) a pound molecule of any univalent compound. The convenience of this close relationship suggests the idea of making it the basis of a unit, the *pound Col.* While this unit is of the same nature as the conlomb, it has merged in it the day as a larger unit of time. He then discusses the proportionality which exists, according to Faraday's law, in electrolysis between the quantity of electricity and the mass, if the latter is measured by gram equivalents. In the light of the relationships which are known to exist between conductivity in electrolysis, osmotic pressure, vapor tension and the raising and lowering of melting and boiling points, he thinks it would be of value to have a set of units of electrical quantities related to or dependent upon a unit quantity, by weight and volume, of hydrogen, which in turn is related to the gram and the c. c. of water by a constant figure. He has found that 100 ampères in one day free 1 c. c. of hydrogen ,and he says that when figuring out this from the most reliable esperimental data one finds this relation to be exact. He therefore suggests to make this a new unit, and, as the weight is a kilocrith, he calls it a kilocrith Col. He suggests a whole system of new units. For instance, he proposes to create a table of "apparent relative atomic capacities for electricity," similar to the table of atomic weights. From such a table thermal reactions or energy transformations would be read with the same ease that we now read and trace the shifting of mass in chemical reactions. It is this relation—that 100 ampères in one day free 1 c. c. of hydrogen—which the author discusses in the second part of his paper, endeavoring to find a physical reason for this relation. It is evident that this must be an extremely complicated matter, as here very different units of physical science are interlinked. Mr. Cowles goes on to put together the relations existing between the units which enter into the problem, but, as mentioned before, he is unable to find the last connecting link. Concerning the details, we must refer the reader to the full paper, which will be printed in the "Transactions of the Society."

The paper was discussed by Messrs. Whitney, Bancroft, Hering, Reed, Richards and Keith, most of whom considered the relations pointed out by Mr. Cowles to be very interesting, but accidental.

The last paper of this session was read by Edward R. Taylor, on "A Closed and Continuous Working Electric Furnace." The author points out that continuity of operation is very important, and almost an absolute necessity for most

chemical manufacturers. Movable electrodes in a closed electric furnace present serious difficulties in this regard. He early thought of using pieces of conductive material that can settle down upon each other from above, and properly arrange themselves and feed down by gravity. He decided to carry the current into the furnace by the use of a stationary conductor of moderate size, and to separately arrange the moving portions inside of the furnace itself. In his former paper, read at the Philadelphia meeting of the Society, he presented a plan of prolonging the life of the electrodes by regularly feeding upon them and at their ends, by gravity, broken conductive material. In his present paper he describes what is practically a continually self-renewing electrode in a closed furnace, the broken and moving portions in their continual descent themselves constituting the electrodes. New material constantly descends and takes the place of that exhausted at the ends of points of wear. The conduits through which these broken pieces are fed are suitably connected by an insulated conductor through the shell of the furnace to the source of electricity. Suitable hoppers are made above the conduits and outside of the furnace, through which the broken conductive material can be fed into, and ultimately through, the several conduits, at the bottom of which the broken fragments are free to arrange themselves by gravity, so that the weakest part of the circuit will be determined where the pieces come together at the bottom of the furnace. As fast as the lower ones are exhausted, others feed down from above and take their place. A second requisite for an electric furnace that shall be capable of continuous and prolonged use, without stopping to clean out, is that either a non-volatile product or residue may be removed from the furnace, either continuously or at intervals, in a fused or molten state. Provision is made to increase or reduce the resistance of the furnace at will by feeding conductive or non-conductive material through openings provided in front of the conduits down upon the working ends of the electrodes, so that comparatively quick changes can be made in the resistance of the working furnace. Mr. Taylor stated that, with less nerve on his part and less actual risk of failure than it required to build the furnaces he operates at present, he could now construct a continuous electric furnace that would dwarf the largest blast furnace in existence. (An illustrated description of the latest form of his furnace is given on another page of this issue. See also the notes on his latest patent in the Analysis of Current Electrochemical Patents.)

## THURSDAY'S SESSION.

The first paper of this session was on "Pumps and Other Accessories in Electrochemical Processes," by David H. Browne. In the absence of the author, it was read by W. McA. Johnson. A longer abstract of this paper is given on another page of this issue. It was discussed by Messrs. Keith, Hering, Johnson and Richards. Dr. Keith and Mr. Hering pointed out the advantages of the compressed-air lift system for such solutions, which is of special value when the aeration and resulting oxidation of the solution is desirable. Mr. Johnson said that steam injectors are suitable in some cases.

The next paper was on "Electrochemical Polarization," the author being Prof. J. W. Langley. In his absence, the paper was read by H. N. Potter. The author mentions Reed's definition of electrochemical polarization as a progressive change in the composition and e. m. f. of an electrochemical system necessitated by the progressive exhaustion of one or more of the electrochemical reagents. He takes exception to the importance given to the idea of progression as an essential part of the phenomenon. The phenomenon of polarization is generally considered to occur instantaneously upon the passage of a current through an electrolyte, and it usually reaches a limiting value very soon. The solution begins to be altered at the face of each electrode instantaneously, this change being always of such a character as to make the cell act as a primary battery, with its e. m. f. opposed to that of the e. m. f. which is driving the electrolyzing current. This is true even in the case of so-called non-polarizable electrodes; for instance, when a current is passed through a cell containing two zinc plates in zinc sulphates. He describes the following method for measuring the counter e. m. f. of polarization. A current is passed through an electrolytic cell, and by means of a quick acting commutator the feeding current is interrupted, and then, almost instantaneously, the electrodes are connected in series with a condenser. The circuit between the electrodes and the condenser is then broken, and the latter discharged through a ballistic galvanometer. The commutator is arranged to do all this by a single movement of the switch, and in a very brief interval of time. The observer thus obtains the voltage of the charging current, and about one-tenth of a second later the counter e. m. f., caused by the chemical products corresponding to polarization. He gives the results of a series of experiments in form of diagrams, in which the abscissas represent the applied volts of the electrolyzing current and the ordinates the polarization voltage. The experiments were made with various solutions, and also with fused salts. The general character of the curves is that, first, the polarization voltage rises with an increase of the charging voltage as a nearly linear function, later less rapidly, and finally reaches a constant value. This constant value apparently indicates that then the entire stratum on the face of the electrodes, and of the thickness of at least the radius of molecular attraction, is occupied solely by the chemical substance at that face, *e. g.*, for pure water a solution of oxygen at the anode and a solution of hydrogen at the cathode. Prior to this time the film is only partly composed of these substances, some of the original liquid still being present. The author is opposed to considering ohmic resistance as forming any part of electrochemical polarization. The method of discharge seems to be the only one, but, as the polarization should be regarded as the instantaneous value of the counter e. m. f. existing during the passage of the electrolyzing current, the above method, by discharge, will always give too low results, because there is a certain, although very small, time interval between cutting off the electrolyzing current and cutting in the condenser.

The paper was discussed by Messrs. Hering, Reed, Cowles, Potter and Richards, the principal point of discussion being the definition of polarization. Mr. Potter criticised the experimental method, as the existence of an indefinite time element introduces a doubt with respect to the experimental results.

The last paper of the session was on "Some Phenomena of Electrolytic Conduction," the author being C. J. Reed. As Mr. Reed, the very active secretary of the Society, was compelled to leave for home on that very morning, on account of sickness, his paper was read by Carl Hering. The author starts with some general remarks on oxidation and reduction as representing the true electrochemical action. He compares, with the aid of diagrams, two different views which are held on the details of the mechanism of the migration of the ions. He calls the one that of Faraday, and the other that of the dissociation theory. He then describes experiments which he has made, the principal one being as follows: A receptacle is divided into various compartments, filled with electrolytes, the end compartments containing the electrodes, so that all compartments are in series. For the sake of simplicity (although Mr. Reed's apparatus is more complicated), we may assume that there are three compartments in series, separated from one another by diaphragms. In the middle and cathode compartments we have a solution of sulphuric acid; in the anode compartment we have copper sulphate. The density and composition of the copper sulphate solution in the anode compartment are artificially held constant during the test. When a current is sent through this system it is easy to calculate what should happen if the whole process consisted in a traveling of H, Cu and $SO_4$ ions with their respective mobilities, which have been determined by previous investigators. As the H ions have a much

...ander and the $CO_3$ ions a smaller velocity than the $SO_4$ ions, ...simple calculation shows that one should expect that the ...ge of the solution of the middle compartment and the con... of $SO_4$ to the same should decrease. This was, however, ... the case in Mr. Reed's experiments. Just the opposite took place, and the volume of this compartment continually increased.

Although Mr. Reed had simply stated the fact and its disagreement with the simple calculation mentioned above, most of the speakers who discussed the paper appeared to regard it as intended to overthrow the electrolytic dissociation theory, and endeavored to show that the results of the experiments do not prove the incorrectness of this theory. Messrs. Hering, Potter, Cowles, Johnson and Richards participated in the discussion. Mr. Hering pointed out that Mr. Reed's experiment did really not represent a test of the dissociation theory, but was a sort of determination of the ionic velocities. In such a determination the nature of the porous diaphragms is of great importance. It was also pointed out that Mr. Reed did not take into account the phenomenon of electric endosmosis, which is known to exist. Mr. Potter expressed the opinion that Mr. Reed's apparatus was of such a construction as to necessarily introduce sources of error. He thought that heat affects may have been the cause of the increase of volume. Professor Richards thought that the use of the word "dissociation" for ions in solution is unfortunate, and explained the difference between chemical dissociation and electrolytic ionisation by means of mechanical analogies. Mr. Reed will certainly reply in the *Transactions* in a communicated discussion.

At the close of the session, Mr. Hering moved resolutions of thanks, for courtesies received, to the Local Entertainment Committee, the Ladies' Committee, the Niagara Power Co., the Niagara Falls Hydraulic and Mfg. Co., the National Food Co., the International Acheson Graphite Co., the Carborundum Co., the Electrical Lead Reduction Co. and the Atmospheric Products Co. The meeting then adjourned.

## PUMPS AND OTHER MECHANICAL ACCESSORIES IN ELECTROCHEMICAL PLANTS.

In an American Electrochemical Society paper, which is valuable on account of the large amount of technical information given in it concerning details, David H. Browne, Cleveland, Ohio, points out that the successful conduct of any electrochemical process depends to a large extent upon the practical solution of the mechanical problems involved. He gives in a humorous style a very interesting account of his struggles with pumps, heaters and other mechanical accessories, as he had to handle for several years a hot concentrated solution of chloride of copper and nickel, with some free chlorine, some hydrochloric acid, and a lot of impurities, such as sand, graphite, copper sulphide, metallic particles, chips of wood, etc.

First, he records a long series of unsuccessful trials with various arrangements, all of which had to be finally discarded; but when this paper will be printed in full, it will be interesting reading, because the author not only describes the unsuccessful arrangements, but also says why they were unsuccessful. When the problem of evaporating and concentrating large amounts of solution became important, they devised a concrete evaporating pan of the following construction. The base of this evaporator was built of brick, the top course being laid in cement, and a cement coat with a slight slope to the front being laid over the top of the brickwork. On this platform was built a shallow concrete pan with sloping sides; a wall down the middle divided this into two equal compartments, which communicated with an opening in the party-wall; they were covered by heavy tiles. While the solution is flowing through, any crystals settling out are raked off the bottom up the sloping sides to a trough. A chimney assists in drawing a current of hot air from the brick oven heated by an oil burner. While this apparatus was successful to some extent, there were two sources of trouble: the coating of the solutions with a floating layer of crystals, and the cracking of the concrete due to alternate heating and cooling. The trouble due to the coating of salts covering the surface of the liquid suggested to them an idea of an evaporator in which a very thin film of solution is continually exposed to a stream of hot air.

The apparatus consists of an iron shell, closed at the upper end by a circular lip, and at the lower end by a similar, but more shallow lip. This shell is lined with bricks and cement and is rotated by a peripheral driving gear. An oil burner in a brick furnace to one side produces a current of hot air, which entering the evaporator by a sleeve, passes along the top of the arch, meeting there a film of liquid which is continuously dragged up from the pool. The solution flows in continually and flows out continuously over the lip through a ring opening around the air sleeve. Any crystals separating are carried in suspension into a tank where they settle out, while the solution passes on towards the pump pit. At first they used a fan to draw the air through, but they found out that better results were obtained by checking the air flow to such an extent that the exit gases were nearly saturated with moisture. He recommends this apparatus as very satisfactory; for further details and illustrations we must refer the reader to the full paper.

When a pump is made of parts—generally three main parts—he recommends to assemble the three main parts in a box, laying the pieces close together without gaskets between. Around these pieces granite concrete is rammed, and the block allowed three or four days to harden before removing the box. To provide for the bolts which hold down the valve checks and the piston gland, short pieces of iron pipe may be laid in the box before the concrete is rammed in, or still better, T-shaped slots may be provided in the concrete by suitable wooden forms nailed against the side of the mould. A three-piece pump so mounted is practically one solid block of stone. It requires no fastening, can be laid on the floor anywhere, and is very readily lined up beneath a driving shaft. As a gasket for this style of pump he has found common felt well soaked in P. & B. paint to be a good substitute for hard rubber.

Recently, they also used pumps made in one piece. Such a pump is very easily mounted in a concrete block. One end is provided with a skeleton ball check, which acts both as a check and discharge opening. The exit pipe is coupled to this by a flat flange and hard rubber nipple. To hold down the check and the piston gland they use a heavy cast-iron plate with two claws on each side, against which the bolt heads or washers can be drawn up. This makes a very compact form of pump mounting.

As a suction pipe he uses either a section of a wood pump log drawn tight against the lower part of the pump body, or a hard rubber flange and nipple coupled to a length of flexible hose of sufficient wall thickness to withstand the collapsing strain. For discharge pipe he uses almost exclusively a permanent concrete main.

## ELECTROCHEMICAL LECTURES.

**Franklin Institute.**—Among the papers announced on the preliminary programme of the sections of the Franklin Institute of Philadelphia we note the following: Dr. J. W. Richards, Bethlehem, and C. M. Hall, Niagara Falls, "The Electrothermic Production of Aluminum from Bauxite;" Dr. Harry F. Keller, Philadelphia, "The Synthetic Production of Perfumes and Flavoring Matter;" W. E. Ridenour, Philadelphia, "The Influence of Bleaching Agents on the Tensile Strength of Textile Fibres;" Miss A. L. Turner, Philadelphia, "The Electrolysis of Di-sodium Phosphate;" A. C. Johnston, Philadelphia, "Ore Handling;" Dr. H. C. Jones, Baltimore, "What Physical Chemistry Has Done for Chemistry."

# ANALYSIS OF CURRENT ELECTROCHEMICAL PATENTS.

By George P. Scholl.

### Electric Furnaces and Furnace Products.

*Reduction of Metals from their Ores, etc., in Electrically-heated Furnaces.* Ramon Chavarria Contardo, Sevres, France. Patent No. 706,651, July 29, 1902.

This invention, according to the specification, "relates to a process and apparatus for the production of metals directly from their ores, and more particularly to a process for producing cast iron or steel of any desired degree of hardness directly from iron ore without the use of solid fuel." For this purpose the inventor, who is a doctor of laws, a citizen of the Republic of Chile and residing in Sevres, France, constructs a furnace, very much like a blast furnace in cross section, in which he proposes to furnish the heat necessary for the melting of the charge by means of the electric arc. This heat is to act only by convection and radiation, as the material itself does not come into contact with the arc, the electrodes being carefully protected by shields. To accomplish the reduction of the heated ores he proposes to introduce into the bottom of the furnace, below the electrodes, a current of dry hydrogen or carbon monoxide, obtained from a suitable generator. He also states that in the particular case where the furnace is to be used for the production of cast iron or steel, it is necessary that carbon combine with the iron and that this may be attained by introducing into the reducing-gas current an easily proportionable quantity of a hydrocarbon in the form of gas or vapor, by which procedure it is claimed that the exact quantity of carbon required can be combined with the iron. From the above description it can already be inferred that the process in question appears to be one of the many which have been proposed for the utilization of the electric current in the metallurgy of iron, but which have never been heard of in practice. Besides using a temperature much beyond anything required in the iron business, the process presents metallurgical and practical difficulties which are almost or quite unsurmountable. There is certainly no need of apprehension on the part of stockholders of iron and steel companies, as long as such complicated and expensive processes are proposed to take the place of the simple and well-developed processes used at present in the metallurgy of iron. The problem seems to be an attractive one to inventors, especially those who are not metallurgists by profession, although there is probably less chance for electricity to be applied in the manufacture of iron and steel than in that of any of the other metals.

*Electric Furnaces.* Arthur Parker, Chorley, England. Patent No. 706,099, August 5, 1902.

The inventor describes a new form of carbide furnace, designed, according to him, to secure a more complete, perfect and continuous fusion of the raw material. The furnace is a crucible furnace, lined perfectly with carbon, and so arranged that it can be slowly rotated around its vertical axis. The carbon electrode is as usually arranged in such a manner that it can be moved upwards as the melted charge fills the crucible. The main characteristic of the furnace seems to consist in the shape of the carbon electrode employed, which is described as being oblong in cross-section, either rectangular or oval. As the furnace is rotated, each part of the charge comes successively within the range of the electric arc, over and over again. The inventor lays special stress on the fact that the arc is not struck between the electrode and the crucible through the material, but between the electrode and the melted carbide, and that, therefore, the carbon electrode does not come into contact with the material through it the whole operation. The material to be fused is delivered into the crucible in a thin stream on both sides of the oblong carbon electrode through hoppers and tubes composed of an insulating material, and it is intended to have it fall down through the arc and thus become fused before reaching the bottom of the crucible.

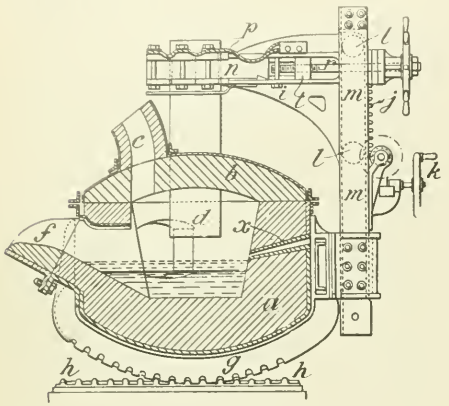
*Electric Furnace.* Edward R. Taylor, Penn Yan, New York. Patent No. 706,128, August 5, 1902.

This furnace embodies various improvements on the inventor's previous furnace, and is to be used primarily for the production of carbon bisulphide, though according to the specification it may be used for other reductions and reactions. Mr. Taylor has had an experience of many years in the manufacture of carbon bisulphide, and deserves great credit for the successful application of electricity in a case where the existing methods were of a most unsatisfactory character. The furnace described in the present patent is used by him on a large scale at Penn Yan, New York. The construction shows a central shaft, through which the charcoal or coke is delivered into a larger working chamber. Concentric to this shaft is arranged a circular space for the feeding in of the sulphur, while several more concentric passages, serving the same purpose, are arranged around the working chamber. The object of this construction is to utilize the heat generated in the working chamber also for the heating and melting of the sulphur, which is delivered by the various passages at different levels in the working chamber. By this means the sulphur is brought into contact with the carbon at a number of places, and the best possible conditions for the reaction are realized. The current is introduced into the furnace by four electrodes, 90° apart, which are constructed in the form of a metallic trough, lined with carbon bricks on three sides and covered with a non-conducting cover on the side towards the interior of the furnace, which arrangement prevents the current from passing directly from one electrode to the other in the upper part of the furnace. These electrode troughs serve at the same time as passageways for the granular conductive material, which is fed into them continuously, and which, after leaving the electrodes, spreads itself out on the bottom of the working chamber and is there heated by the current to the proper temperature. For the protection of these passageways and the regulation and control of the operation of the furnace there are arranged passages running above and parallel to them, by which either conductive or non-conductive material can be introduced into the working chamber and can thus be brought right in front of any or all of the electrodes. The specification is one which will recommend itself to any practical man for the clear statements it contains, which are all to the point and bear witness that the apparatus it describes is a product evolved from actual practical conditions. It shows in this respect a marked contrast to many others, which are unhappily too full of glittering generalities in which the respective inventors allow their fancy to run riot.

*Oscillating Electric Furnace.* Paul L. Héroult, La Praz, France, assignor to Société Electro-Metallurgique Française. Patent No. 707,776, August 26, 1902.

Héroult, the well-known electro-metallurgist and inventor of the Héroult aluminum furnace, describes in this specification the construction of an oscillating electric furnace, which is to be used among other purposes for the manufacture of steel. As shown in the adjoining diagram, the furnace consists of a crucible *a*, provided with a cover *b*, a small chimney *c*, and a spout for running off the metal on tilting the furnace. The bottom of the furnace is arched and cogs on rails engaging with cogs on rails *h* are arranged for effecting the tilting. The carbon electrodes *d*, surrounded by a collar *n* of sheet

which the copper wedges serving to convey the current from the cables *p* to the electrodes, are carried by arms *i* projecting from sliding uprights *j*. The uprights *j* are guided by rollers *l* in a standard *m* of trough-shaped section, and can be worked by a worm and hand wheel *k*. A screw spindle *r* and nut *t*, turned by a hand wheel, provides for the tightening and loosening of the collar *n*. In order to use the

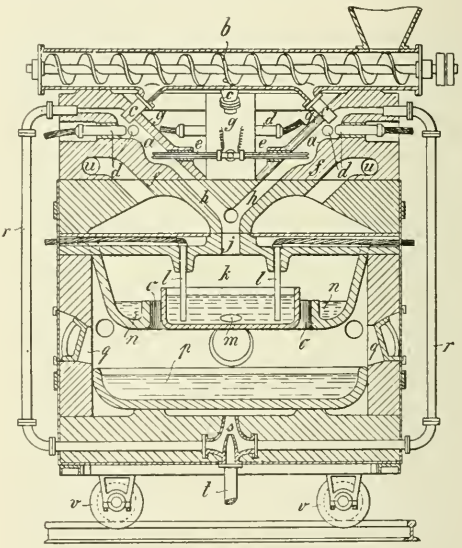


HEROULT FURNACE.

furnace for bessemerizing, a wind chest is arranged at the back of the furnace, from which tuyeres *x* lead into the working chamber. The tuyeres open ordinarily above the level of the bath, but are submerged when the furnace is tilted back in order to carry out the Bessemer process. Though anything coming from Héroult is entitled to serious consideration, it seems that the use of electric furnace in a process which has been brought to such perfection in the working and handling of enormous outputs as bessemerizing has been is an undertaking which will have to contend with many difficulties. It is proposed to use a pig iron, which, as the specification says, "need not contain either phosphorus or silicon," which probably means pig iron low in phosphorus and silicon, as it would be impossible to find a pig iron in the market which does not contain either of these elements. Such pig iron can be used, as it is not necessary in the electric furnace to depend on the oxidation of the silicon in the acid converter or the phosphorus in the basic converter in order to furnish the necessary heat for the process, which heat is, in this case, supplied by electricity. Pig iron of this kind could, of course, be obtained at a lower price than that used ordinarily in bessemerizing, but this difference would hardly be sufficient to make up for the increase in cost due to the use of electricity. The last judgment in this case will have to be pronounced before the tribunal of practice.

*Electric Glass Furnace.* August Voelker, Cologne, Germany. Patent No. 705,283, August 5, 1902.

Within the last few years several furnace constructions have been patented in different countries, having for their object the utilization of the electric current in the manufacture of glass. The name of the inventor of the furnace under consideration has already appeared in the patent literature in this connection, and the furnace is evidently an improvement on his earlier constructions. The apparatus as shown in cross-section by the adjoining figure, shows a worm conveyor *b*, by which the materials for forming the glass are delivered to four tubes *c*, which lead into inclined radial passages *h* over what the inventor calls the "hearth" *a*. These passages are formed by four refractory blocks *f* and are covered by slabs *g*. There the material is melted by the heat of arcs between the electrodes *d* and by arcs of so-called jablochkoff candles *e*. The material flows down through the passage *j* into the refining vessel *k*, where the melt is kept fluid by the introduction of another alternating or direct current by means of the electrodes *l*. Here the principle of resistance heating is employed. From *k* the melt flows by openings *m* into the circular trough *n*, whence it overflows by the passages *o* into the lower vessel *p*, where it is worked by tools through the working doors *q*. The vessel *p* is heated by the burning under it of the combustible gases which are evolved in the passages *h*, and are conducted under it by the pipes *r*. The burning is effected by a suitable burner *s* provided with an air-pipe *t*. The apparatus is mounted on wheels *v*. *U*, *u* are channels through which such incombustible gases as are evolved pass off.



VOELKER GLASS FURNACE.

The furnace under consideration removes one objection which has been urged against several other constructions, namely, that no provision was made for a thorough liquation of the glass after melting, which is just as important for getting a good product as the melting itself. This, as it appears, has been amply considered by the inventor. There may be a question whether the use of a separate electric current for keeping the melt liquid will pay in practice; in all cases it seems that a direct current would be objectionable if the inventor should have intended to avoid all danger of possible electrolytic effects. It is also difficult to see how the serious objection arising from the contamination of the melt by carbon dust or carbon particles falling down from the electrodes can be overcome in a satisfactory manner.

*Manufacture of Glass by Means of Electricity.* Yegor Broom, Cologne, Germany. Patent No. 708,309, September 2, 1902.

The present furnace is designed, according to the inventor, to overcome the difficulty which is encountered in previous constructions in that the mixture became agglomerated by partial fusion before it reached the electrodes. In consequence of this it had to be pushed forward, thus arriving at the electrodes intermittently, and not only subjecting them to variable strains, but causing much carbon dust to fall into the glass melt and contaminate it. The inventor proposes to overcome these difficulties by using the mixture in the shape of compressed balls, etc., or of a continuous moving rod. He

arranges a mixing apparatus where he mixes the raw material with a suitable binding material, then it is passed through one pair of rollers where it is compressed and a second pair of heated rollers where it is dried. From there the material passes in a continuous-moving strip between or beneath the electrodes of the furnace, where it is melted by the heat of the electric arc. It would seem from this construction that there still exists an opportunity in this apparatus for the melt to become contaminated by particles falling into it from the electrodes. The construction is open to objection for the reason mentioned above, namely, that no provision apparently is made for the liquation of the glass melt, unless it is intended to perform that process in another apparatus heated by ordinary means. The patent is assigned to the Gesellschaft zur Verwerthung der Patente für Glaserzeugung auf electrischen Wege, Becker & Co., Cologne, Germany, who own several other electric glass processes.

### Apparatus and Processes for the Electrolytic Production of Metals and Compounds.

*Process of Manufacturing Manure from Apatite or Similar Mineral Phosphate.* Johan Gustav Wiborgh and Wilhelm Palmaer, Stockholm, Sweden. Patent No. 707,886, August 26, 1902.

The process as described aims at the formation of an easily-soluble phosphate from apatite or other hard soluble mineral phosphates by electrolysis. For this purpose the inventors use as electrolyte a salt which, on electrolysis, furnishes at the anode an acid capable of forming a soluble salt with lime and at the cathode a basic hydrate. As electrolyte they prefer alkaline or ammoniacal salts which contain, for instance, nitric acid, chloric acid or perchloric acid. The mineral phosphate is placed "in a suitable manner" near the anode and the acid liberated there is supposed to dissolve it. When this solution comes into contact with the cathode liquid, where the alkaline hydrate has been formed, the dissolved phosphate of calcium is again precipitated, but this time in another form, as a white flocculent precipitate which is easily soluble in citric acid. It is said to be advantageous to use a porous diaphragm, so as to prevent the precipitate from going over towards the anode and being redissolved. It is claimed that the electrolyte remains nearly unaltered, but as that is usually claimed by all inventors and so rarely found true after a process is introduced into practice, and as no reactions are given to support that assertion, the statement will have to be verified by actual demonstration. That complex salts like the chlorates or perchlorates should be so easily reformed is somewhat hard to believe. If the salts should not be reformed, then the use of high priced electrolytes for the manufacture of a cheap product will naturally be inadmissible. The question of apparatus is, of course, not considered in this spirit, which is a process patent only, but it would be interesting to know in what manner the inventors have succeeded in overcoming the difficulties about placing the material "in a suitable manner" near the anode, so that the anion will act on it. This alone has been the stumbling block of a good many processes already. It seems also that the cost of power would be very high as compared with the price of the product, as the resistance of the bath will undoubtedly be great, due to the fact that a diaphragm will have to be used and that the anode has to be practically surrounded by a non-conducting substance, to wit, the material to be acted upon

*Apparatus for the Electrolytical Treatment of Ores or Slimes* Frank T. Mumford, Kalgoorlie, Western Australia, Australia. Patent No. 706,436, August 5, 1902.

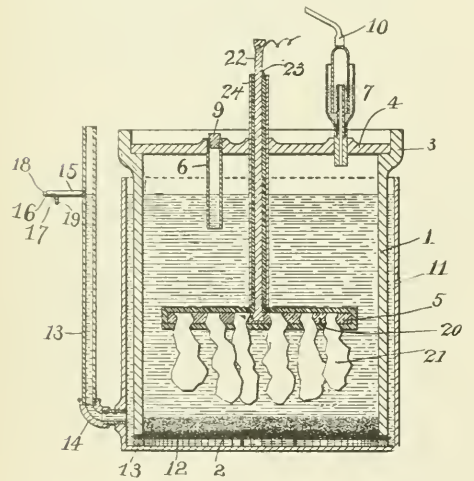
The invention, according to the specification, relates to an apparatus for the treatment by electrolysis of ores and slimes for the extraction of precious metals, particularly gold, therefrom, whereby the solution of the precious metals from the ore and its deposition are effected by the aid of mercury in an easily recoverable condition. The apparatus is said to be applicable for the treatment of any auriferous ore, but to be especially valuable in the case of a slimy and clay-like ore which requires very fine crushing. The apparatus consists of a steel cylinder lined on the inside with amalgamated sheet copper, and having at the bottom a layer of mercury. This cylindrical shell forms the cathode of the apparatus, while the anodes are formed by a number of carbon or iron rods, passing insulated through the closed ends of the cylinder and running parallel to the sides. The cylinder can be rotated about its horizontal axis. As electrolyte is claimed a solution of cyanide of potassium or sodium, chloride or bromide of sodium or other suitable salts, either jointly or separately. The operation is described as follows: The cylinder is filled with the crushed ore and electrolyte, and started to revolve slowly. The current is then introduced, which is expected to dissolve the gold by means of the anion liberated and deposit it as amalgam on the cathode. Any coarse particles of gold in the ore are supposed to be immediately amalgamated by contact with the mercury. At the end of the operation the mercury is run off, the amalgam squeezed out and retorted. The process, on reading the specification, appears to be as easy, as is termed in the common vernacular, as rolling off a log. One fills the gold ore and electrolyte into the cylinder, turns on the electricity, turns the crank, as it were, and finds the gold at the end in the mercury. But when one recalls the legions of apparatus of similar construction which have been patented for the same purpose and have died a peaceful death in the archives of the Patent Office, one cannot help but feel a little skeptical about the practical success of this one.

*Electrochemical Apparatus.* Chauncey C Clark Philadelphia, Pa. Patent No. 706,520, August 12, 1902.

The object of this invention is to construct a closed apparatus for the electrolysis of chemical solutions, as the production of bleach liquors by the release of chlorine from common salt, the electrodes and their connections being kept at a low temperature. It is said that in consequence of the low temperature the electrical resistance of the electrodes is so largely diminished that the life of the electrodes and their connections is greatly prolonged. The apparatus consists of two copper or iron cylinders, one within the other, so that the inner one is completely surrounded by cooling liquid. In addition to that the inner cylinder is traversed lengthwise by copper tubes, arranged similar to the tubes in a tubular boiler, which tubes serve also for the circulation of cooling liquid. The electrodes are screwed to bars running the whole length of the inner cylinder, parallel to the tubes and the electrode material is platinum for the anodes and zinc for the cathodes. The cooling fluids enumerated are "liquid air, ice water, compressed air or other suitable or available cooling fluid or material." This is the gist of the invention, but enough will be gathered from this to show that the inventor has upset all our ideas about the electrolytic production of bleaching liquors and the chemical action of the product obtained thereby. Up to now we had supposed that free hypochlorous acid, which, according to Foerster and Bischoff's researches, exists in bleaching solutions prepared by electrolysis and to which their strong bleaching action is due, would energetically attack metals like zinc and copper and destroy them in a very short time. Preceding inventors in that line had proposed various apparatus and had to cool their solutions in order to prevent the formation of chlorate, though they could not afford to use liquid air or ice water. Then a high current density and reversible electrodes as in the well-known Kellner apparatus were supposed to be absolutely necessary. Furthermore, it was thought that sheets of platinum of sufficient strength to resist for any length of time as electrodes were prohibitive as far as their cost was concerned, a reason why Oettel used carbon electrodes in his apparatus. An active circulation of the electrolyte was also considered necessary. This is all done away with in the apparatus under consideration. It would perhaps be interesting to look into it after a current of say 200 amperes has been going through it for half a day and see what happened.

*Electrolytic Cell.* Adolph Sommer, Cambridge, Mass. Patent No. 707,804. August 26, 1902.

The specification describes a new form of an electrolytic diaphragm cell, which is reproduced in the adjoining figure. The cell consists of an iron tank 11, which forms the outer part of the cell and serves as cathode at the same time. In it is placed a stone or earthenware tube 1, having a flange 3 in which is secured a cover 4, with water-seal tube 7 and replenishing tube 6 closed by cork 9. Through the center of the cover there enters the anode 5, consisting of a metallic base 20, in which a plurality of pieces of carbon 21 or other suitable substance are embedded. A rod 22 is in connection with the metallic base, which rod is covered by a coating of asphaltum or other suitable material 23 and a sleeve 24 of glass, etc., serving to protect the covering. The anode is somewhat smaller than tube 1, allowing space for gas and liquid to pass between. Between the lower end of tube 1 and the bottom of tank 11 are interposed in the order named a sheet of non-fibrous foraminous material 12 and a support 13 of some non-conducting material, as glass, porcelain or stoneware. Upon the sheet 12 and inside of tube 1 is placed a layer of granular material,



SOMMER ELECTROLYTIC CELL.

as crushed glass or quartz sand, just crushed large enough so as not to pass through the meshes of the non-fibrous foraminous sheet. 13 is a discharge pipe with elbow 14 and several small branches 15, 16, 17, 18, 19. The advantages claimed for this apparatus are: First, the tubular anode compartment, making it possible to remove the cover and gain access to the anode very quickly; second, the iron tank which constitutes the cathode; third, the peculiar construction of the diaphragm, which is made of a sheet of foraminous non-fibrous material having small openings and a layer of granular material which lies on the sheet and closes the openings.

### Improvements in Storage-Battery Construction.

*Separator for Electric Accumulator Plates.* Richard A. Katz, Berlin, Germany. Patent No. 705,630, July 29, 1902.

This invention provides a separator for electric accumulator plates of non-conducting material, consisting of a combination of two wide meshed gratings, of which the intersections of the one cross the open spaces of the other. Thus ample space for passage of the electrolyte is assured and the plates are supported at the same time along numerous uninterrupted lines.

*Composition for Use in Secondary Batteries.* Carl Oppermann, London, England. Patent No. 706,444, August 5, 1902.

The object of the invention is to render the active material harder and less liable to disintegration, which the inventor proposes to do by making up the lead oxide into a paste with diluted sulphuric acid and adding a solution of Trinidad asphaltum, preferably dissolved in benzine and diluted with alcohol. After applying the paste to the support he dries it at a low temperature to drive off the solvent of the asphaltum, and claims that this acts as a cement and increases the hardness of the active material.

*Electrode for Storage Batteries.* Charles W. Kennedy, Rutledge, Pa. Patent No. 706,568, August 12, 1902.

The object of the invention is to provide an electrode with a maximum amount of active surface and a minimum amount of weight, which he attains by a peculiar mechanical construction which is described at length in the patent.

*Electrode for Storage Batteries.* Henry Woodward, London, England. Patent No. 707,666, August 26, 1902.

The invention consists in a construction designed to reduce the weight of storage batteries and at the same time to provide better means for retaining the oxide of lead upon the positive and negative plates. The inventor forms the positive plate of his accumulator from thin strips or tapes of lead and claims "an accumulator plate comprising a plurality of strips crossing each other and pivotally connected together to permit expansion and contraction."

### Galvanic Cells.

*Galvanic Battery.* Charles S. Schoenmehl, Waterbury, Conn. Patent No. 705,616, July 29, 1902.

This concerns an improved form of copper oxide cell designed for use in automobiles, etc., in which the electrodes are kept rigid by suitable mechanical means, which allows the use of the cell in any place where it would be subject to rough handling and shaking.

*Electric Battery.* Edward R. Gill, New York, N. Y. Patent No. 705,919, July 29, 1902.

This patent embodies various mechanical features which aim to facilitate the connection of cells in series and the removal of any of them without disturbing the circuit. It is, as the inventor describes it, an improved form of socket whereby cells made in accordance with his invention are quickly and easily put into or out of circuit without interfering with the operation of the battery.

*Battery.* William L. Panikoff, New Haven, Conn. Patent No. 706,340, August 5, 1902.

The specification says: "This invention relates to batteries, and more particularly to that class of batteries in which it is desired to use different strengths of current, and has for its object the construction of a device by which a series of batteries are adapted to be used singly or in series according to the wish of the operator, and that when not in use the plates of the batteries may be held in position free from the flint contained in the jars themselves." A mechanical construction for this purpose is described in detail.

*Electrochemical Generator.* Harry S. Amwake, Camden, N. J. Patent No. 12,019, reissue, August 12, 1902.

The inventor proposes to construct a cell "in which the chemical action shall not markedly exceed the rate at which the electric current is drawn from the cell," and also to "secure a cell giving a high and constant electro-motive force." For this purpose he arranges a current-conducting baffle plate or partition between the electrodes, and claims that "thereby the movement of the electrolyte, due to differences of temperatures between different parts of the same, will take place in a devious or circuitous path, whereas the electric current may pass directly through the conducting baffle from one electrode to the other."

*Chemical Generator of Electricity.* Edward Lacey Anderson, St. Louis, Mo. Patent No. 706,631, August 12, 1902.

The invention consists of a cell with an aluminum and a carbon electrode, and an electrolyte composed of a suitable halogen salt or salts, *i. e.*, a fluoride or chloride, or both—an acid and preferably in practice a depolarizing agent.

*Galvanic Battery.* Eason L. Slocum, Pawtucket, R. I. Patent No. 707,363, August 19, 1902.

The cell is designed to furnish a current either of quantity or intensity, as the inventor provides a containing jar which has five separate positive electrodes and also the negative electrodes made in divisions.

*Electrochemical Generator.* Harry S. Amwake, Camden, N. J. Patent No. 707,372, August 19, 1902.

This is an improvement on the cell described above and consists in using a baffle plate in connection with both the negative and positive electrode, that is to say, in using one baffle to surround the positive electrode or electrodes, and another baffle to surround the negative electrode or electrodes.

*Electric Battery.* Ernest A. G. Street, Paris, France. Patent No. 707,731, August 26, 1902.

The invention provides a detachable vessel to be connected to the electrode of a galvanic cell, which vessel contains the depolarizing agent. By the construction shown in the specification it is possible to renew the depolarizing agent quickly without interfering with the electrode.

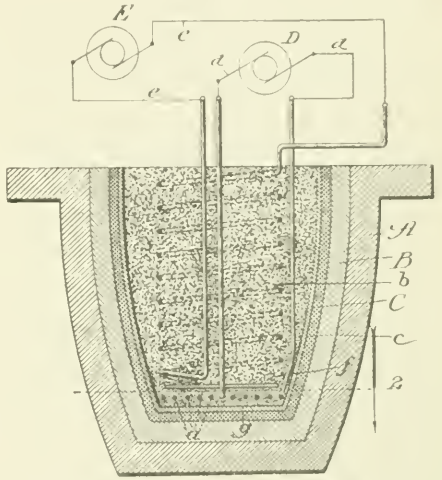
### Miscellaneous.

*Method of Electrodepositing Metal on Lace.* John Andrew Daly, Washington, D. C. Patent No. 707,306, August 19, 1902.

The inventor takes the articles of lace or other flexible material on which he wants to get a metallic deposit and prepares them in the usual manner by coating their surface with an electrical conductor, either by rubbing graphite on them or in another suitable way. He then lays them on a wire basket and winds a number of turns of fine wire around them and the basket. Thereby he brings the articles into contact with the wire and the basket at a great many places and as soon as the basket is made cathode in an electrolytic bath, the deposit starts right away at the contact points and from there spreads over the articles to be coated. He does not allow the current to act more than a few minutes, or just sufficient to give stiffness to the articles, because they would stick to the wire if left too long and would thus be spoiled. After they have been stiffened in this way they may be suspended into the electroplating bath by metallic hooks, and the deposit of metal may then be continued.

*Method of Treating Metallic Oxides in the Production of Metals and Alloys.* Frederic C. Weber, Chicago, Ill. Patent No. 705,727, July 29, 1902.

This invention is claimed to be an improvement in the process of producing metals by reduction of their oxides by means of metallic aluminum. In the Goldschmidt process, introduced into practice by the Allgemeine Thermit Gesellschaft, of Essen, Germany, this reduction is accomplished by mixing finely-divided aluminum with the metallic oxide to be reduced and starting the reduction at one point by igniting a strip of magnesium wire inserted into a cartridge filled with an easily reducible oxide, such as peroxide of barium. The easily reducible oxide is reduced by the magnesium and the heat propagates itself through the entire mass. It is claimed by the inventor of the process under consideration that various disadvantages, such as explosions, contamination of the reduced metal by magnesia, etc., can be avoided by using his method. The arrangement of the apparatus is as follows: *A* represents the outer vessel; *B* the lining of lime or graphite; *C* a lining of mineral wool and magnesia; *D* and *E* two sources of electrical energy. *a* is a coil of small aluminum wire placed in the bottom of the crucible. *b* is a helix of aluminum wire placed within the vessel above the coil, *c* a thimble of aluminum, *g* is finely powdered oxide, *h* is the coarser oxide which is to be treated and *f* is a sheet of tissue paper to prevent the mixing of the fine and coarsely powdered oxide. The process is started by heating the larger coil by means of a current to such a temperature below the melting point of aluminum as to drive all the moisture and water of combustion off. After this a current of sufficient intensity to melt the small



WEBER APPARATUS FOR REDUCING OXIDES.

aluminum coil in the bottom is turned on, with the result that the reaction starts there and propagates itself through the whole charge, producing a molten corundum slag and the desired metal.

## THE CONDUCTIVITY AND FREEZING POINTS OF AQUEOUS SOLUTIONS OF CERTAIN METALLIC SALTS OF TARTARIC, MALIC AND SUCCINIC ACIDS.*

By Prof. O. F. Tower.

In an article which appeared recently in the *Journal of the American Chemical Society* it was shown that the molecular conductivities of nickel and cobalt tartrates in aqueous solution were abnormally small, and also that the freezing-point method yielded apparent molecular weights considerably greater than those calculated from the simple formulas. The explanation was offered at that time that this behavior might be due to polymerization of the molecules. The object of this paper is to see if this behavior is confined to the tartrates alone of nickel and cobalt, and also to see if the nickel and cobalt salts of certain other acids are related to the tartrates. The determinations with nickel and cobalt tartrates have been repeated and determinations have also been made with magnesium, barium and manganese tartrates (these were the only ones of this class found to be sufficiently soluble), and nickel, cobalt and magnesium malates and succinates. The molecular conductivities of these salts at dilutions of 32 and 1,024 liters follow:

MOLECULAR CONDUCTIVITY.

| v | Tartrates | | | Malates | | | Succinates | | |
|---|---|---|---|---|---|---|---|---|---|
| | Ni | Co | Mg | Ni | Co | Mg | Ni | Co | Mg |
| 32 | 10.1 | 15.5 | [illegible] | 58 | 57 | 61 | [illegible] | [illegible] | [illegible] |
| 1,024 | 90 | 115 | [illegible] | 72 | [illegible] | 87 | [illegible] | [illegible] | [illegible] |

The molecular weights calculated from the simplest formula for the respective salts, together with the molecular weights

* Abstract of a paper read at the Pittsburg meeting of the Amer. Chem. Soc'y, July, 1902.

found by the freezing-point method for a dilution of 16 and 32 liters, is given in the following table:

| | *Tartrates* | | | *Malates* | | | *Succinates* | | |
|---|---|---|---|---|---|---|---|---|---|
| | Ni | Co | Mg | Ni | Co | Mg | Ni | Co | Mg |
| Mol. Wt. from formula | 207 | 207 | 172 | 191 | 191 | 150 | 175 | 175 | 140 |
| Mol. Wt freezing point { V = 16 | 236 | 244 | 122 | 164 | 179 | 120 | 168 | 111 | 82 |
| { V = 32 | 196 | 207 | 169 | 140 | 150 | 100 | 160 | 163 | 77 |

In addition to the tartrates of nickel and cobalt, the malates of these same metals show similarly low conductivities and high molecular weights. The succinates of nickel and cobalt act normally, as do the various other tartrates, malates and succinates investigated. These results seem to show that the presence of the hydroxyl groups in the tartaric and malic acids have some effect in causing this peculiar behavior of the nickel and cobalt salts. And the fact that the molecular weights found for the malates seem to indicate that the polymerizing effect increases with increase in hydroxyl groups.

However, after the above work had been finished, similar determinations were made with the nickel, cobalt and magnesium salts of malonic and tartronic acids to see if this would throw any light on the influence of the hydroxyl groups. Tartronic acid is related to malonic acid as malic is related to succinic acid, it was, therefore, to be expected that if the presence of the hydroxyl group tends to cause polymerization of the nickel and cobalt salts, the molecular conductivities of the tartronates of these metals would be considerably less than the molecular conductivities of their malonates, and that the freezing-point method would yield greater molecular weights in the former case than in the latter. The results obtained did not confirm this conclusion.

Although the nickel and cobalt salts possess lower molecular conductivities and higher apparent molecular weights than the magnesium salts, yet the results with the tartronates do not differ materially from those with the malonates. The hydroxyl group, therefore, does not seem to be the determining influence in the peculiar behavior of these nickel and cobalt salts. Just what causes this exceptional behavior of nickel and cobalt tartrates and malates must be left undecided. But there is undoubtedly something in the nature of the nickel and cobalt themselves which causes aqueous solutions of their organic salts in general to offer greater resistance to the electric current than similar salts of the other metals investigated, for example magnesium.

## TESTING CARBON ELECTRODES.

The following is an abstract of a paper read at the Niagara Falls meeting of the American Electrochemical Society, by Francis A. J. Fitzgerald:

In both electrochemical and electrometallurgical processes in which carbon electrodes are used the determination of their density is important. The general efficiency of the electrodes depends on the nature of the carbon and on the methods used in their manufacture, and much may be learned on these points by a determination of the density. Two different densities are to be distinguished; the real density and the apparent density. The apparent density is equal to the weight divided by the volume as a whole. From these two we get the porosity which

$$\text{is equal to the } \frac{\text{real density—apparent density.}}{\text{real density.}}$$

The determination of the *real density* is difficult on account of the persistence with which amorphous carbon and graphite retain air.

The apparatus used in this determination are as follows: a volumeter graduated to 100 c. c. in divisions of 0.2 c. c., and fitted with a rubber stopper through which passes a glass tube, the end of the glass tube inside the volumeter being drawn to a point and bent back; a water bath in which the volumeter is placed to keep the temperature constant; a vacuum pump; kerosene oil, such as "Acme Crown" kerosene, which has a high flashing point and is free from the volatile paraffine. Oil is used in the volumeter because it will not readily wet carbon.

The method of determination is as follows: A specimen of the carbon or graphite to be tested, weighing at least 30 grains, is cut from the electrode and weighed. The volumeter is partly filled with kerosene and is placed in the water bath. A reading of the volumeter is then taken, the specimen introduced and the instrument connected with the vacuum pump. When the pump gauge has shown the maximum attainable vacuum for a period of about ten minutes, the volumeter is disconnected and a second reading taken. The operation is then repeated and another reading taken. This method is followed until two consecutive readings are the same. The difference between the last reading and the original reading is the real volume, and from this the real density can be calculated.

There is no evaporation of oil, but in the beginning a serious loss of weight was found, which was due to the drawing off of a fine spray caused by the bursting of air bubbles at the surface of the oil. This difficulty was overcome by drawing out the glass tube and bending it back on itself.

The pressure is reduced to about 20 mm. of mercury by a filter pump. There is no constant error in the observations due to this imperfect vacuum.

In a determination by this method and by the specific gravity method, the following results were obtained:

Density determined by volumeter..... 2.1887
Density determined by specific gravity..... 2.1930

The *apparent density* is determined by giving the electrode a light coat of shellac, putting it into a volumeter which contains water, and then observing the volume of water displaced by the electrode.

The second part of the paper deals with the detection of amorphous carbon and graphite in carbon and graphite used as electrodes. Graphite shows greater resistance to oxidizing and disintegrating actions than any other form of carbon. To obtain the best results in electrolytic and electrometallurgical work the electrode should contain no amorphous carbon, and it is important to have some method of testing whereby amorphous carbon can be detected. The following is a method suggested by Berthelot: About 0.5 gram of the finely powdered electrode is introduced into a test tube containing 10 c. c. of nitric acid, and to this is added cautiously 4 grams of potassium chlorate. The test tube is then placed in a water bath and kept at a temperature of 60°, until all action is over, that is, for about ten or twelve hours. The nitric acid is then poured off, the residue is thoroughly washed with hot water by decantation and dried. By repeatedly treating the specimen in this way all the amorphous carbon present is converted into a yellowish-brown soluble substance, while the graphite yields a yellow insoluble substance, which has been named graphitic oxide by Berthelot. When a mixture of graphite and amorphous carbon is under observation the presence of the latter is easily recognized by the reddish-brown color of the water used in washing the oxidized products.

In the Acheson graphite electrode there is an entire absence of amorphous carbon, the electrode consisting wholly of graphite.

When it is desired to test an electrode to determine whether it is composed wholly of amorphous carbon or contains a certain amount of graphite a method of Staudenmaier may be used. The specimen to be tested is treated once with the oxidizing mixture, washed, heated in the water bath with a solution of potassium permanganate and sulphuric acid, and finally treated with an excess of hydrogen peroxide. If the specimen consisted wholly of amorphous carbon, a clear solution of a reddish-brown color is obtained, but if any graphite is present there remains an insoluble residue of a yellow or greenish-yellow color.

# SYNOPSIS OF ARTICLES IN OTHER JOURNALS.

*A Summary of Articles on Electrochemistry and Allied Subjects Appearing in American and Foreign Periodicals.*

By Carl Hering.

## INDUSTRIAL ELECTROCHEMISTRY.

*Copper Refining.*—The long series of articles by Philip, of which the first parts were noticed in the synopsis last month, have now been concluded in the Lond. *Elec.*, August 15th, 22d and September 26th. The whole serial is to be published in book form, the portions published in advance being merely portions of this book. The concluding parts are limited to copper refining. Continuing his analysis of the costs he finds that the cost in dollars of dynamos and switchboard, including erection, is 0.28 T D, in which T is the output in tons per year and D the current density used in ampères per square foot. The cost of electrolytic vats is 60 T / D. The cost of the electrolyte required is 0.30 T S / D, in which S is the price of copper sulphate crystals per ton in dollars. The cost of the copper anodes is A T P / D, the thickness of the anode plates in inches being A and the cost of anodes per ton, P. The capital invested in copper in stock, including cathodes and copper leads, etc., is 1.3 A T P / D plus 4.05 R T / B, in which R is the price per ton of the refined copper of which the leads are made and B the current density per square inch in the copper conductors. In an example the price of the refined copper was $375 per ton; the price of anode copper, $350 per ton; the output of refined copper, 1,000 tons per year; the current density, 10 ampères per square foot at anodes; the price of copper sulphate crystals, $125 per ton; the thickness of the anode plate, 1 inch, and 250 ampères per square inch allowed in the copper current conductors; then his formulas give the total capital invested as $50,125. He then discusses the various items in the annual cost of refining. There is first the interest on capital invested; there is no depreciation except in so far as the market price may vary, but this cannot be readily taken into account; the annual cost of labor is 0.6 W T, in which W is the amount paid weekly in wages. The annual cost of melting refined copper is 1.25 M T, where M is the cost of melting one ton, and the factor 1.25 is to allow for remelting scrap anodes. The cost of fuel used for power per year is 0.0771 T D C, in which C is the cost of coal per ton. He then points out the great influence which the current density has upon the capital and annual outlay per ton of copper refined per year; there is, in fact, some particular current density which will yield the most satisfactory financial results, and this particular one varies with the price of coal, the cost of melting down each ton of refined copper into ingots, the rate of wages paid, the rate of interest paid upon the capital invested, and lastly, but most important, the difference in price at the works between the price paid for anode copper and the price obtainable for the refined copper, together with the value of the silver and gold separated from it, if this value goes to the refiner. The current density at the anode used in different plants varies between 1 and 15 amperes per square foot. He refers to a statement of Cowper-Coles that whereas formerly current densities of only 2 to 4 ampères per square foot were thought permissible, current densities of from 15 to 20 ampères are now said to be used in some establishments. The author states that he does not know of any electrolytic copper refinery in which a greater current density than about 15 ampères per square foot has been successfully used over any length of time, and he is strongly of the opinion that it cannot pay to use a greater current density than 16 ampères per square foot at the outside, if the product of the refinery is merely pure refined copper, and not, as in the Elmore process, some manufactured, or partly manufactured, article of copper, like sheets, tubes, wires, etc. He uses his formulas for calculating the different items of the capital investment and the annual charges, to show how all these items vary, when the current density is varied between 5 and 20 ampères per square foot, and from the results obtained it appears that the percentage profit on the capital invested, under the particular conditions stated, will be greater when the current density at the anode is about 15 ampères per square foot. The increase in the current density is not only limited by the question of prime cost, interest and depreciation, but also by other important factors, such as the alteration of the mechanical character of the electro-deposited copper on the cathode and the alteration of its chemical nature when the current density increases. Unless some special means are used, the copper which is deposited with current densities much above about 14 or 15 ampères per square foot, tends to take a crystalline and loose form, finally becoming long growths which may short-circuit a vat. Furthermore, if the electrolyte contains many impurities the high current density is favorable to the precipitation of arsenic and antimony together with the copper, thus greatly reducing its value. Concerning the series and parallel arrangement of the vats, he says that the amount of copper used in the connections between the vats and the dynamo is greater in direct proportion to the number of sets of vats there are in parallel; and the amount of copper in the form of copper is also greater per ton output of copper the greater the number of vats used on account of the extra connections between each vat. Economy in copper is, therefore, attained by having all the vats in series and having the vats as large as possible. The amount of copper is also less the greater the current density. He finally makes a few remarks on the size and the number of the vats and on the best voltage of the dynamos used for copper refining.

*Zinc Plating.*—To electrochemists, at least to those who have studied the relative electrochemical behavior of various metals, it is well known that when iron is in contact with zinc, or any other more electropositive metal, the iron cannot rust, as there exists continually an electrochemical-reducing action at the iron, at the expense of a corresponding oxidation of the zinc, and it is for this reason that galvanized iron does not rust. But this is also the reason why iron which has been covered with zinc by mere insertion in molten zinc is called "galvanized." The term galvanizing, as often applied to the process of coating the iron with zinc by dipping in molten zinc, is therefore quite irrational, as the only galvanic action which exists is the subsequent electrochemical-reducing action when the galvanized or electrofied iron becomes moist, and as the metal is then always cold the term "cold galvanizing," which is now often used for the process of electroplating with zinc, is therefore used for just the reverse process to which the term strictly applies, namely, for the reduction instead of the oxidation of the zinc. Similarly the term "electrogalvanizing" is quite incorrect, it being tautological. While such incorrect words may get into our not too consistent English language through the commercial elements, yet there seems to be no excuse why they should be sanctioned by electrochemists who understand their true meaning and origin. However this may be, a recent article by Burgess and Hambuechen in the *Electrical World and Engineer*, September 13th, under this unfortunate heading, is decidedly better than its title. In this they first discuss the prevention of the corrosion of iron by means of a coating of zinc and the advantages of the electrolytic

deposition of zinc over the hot process. The commercial processes by which "electrogalvanizing" is now being performed may be subdivided into two classes, according to whether use is made of soluble or insoluble anodes; the former is used almost exclusively in this country and the latter in England. The Cowper-Coles process employs a lead anode, which is practically unattacked by the sulphate solution, so that free acid is continually formed. The acidity of the solution, which is drawn from the tanks, is neutralized by bringing it into contact with zinc dust in contact with coke. The reason for prefering a soluble zinc anode is that circulation and regeneration of the electrolyte are theoretically unnecessary, and the use of auxiliary apparatus is done away with to a considerable extent; the amount of power required is also considerably smaller. The objections to zinc anodes are two: first, during the operation there forms upon the surface of the zinc a scale or coating, usually black in color, which interferes with the dissolution of the zinc; second, for satisfactory operation the solution must be kept at a certain degree of acidity. The deposition of a good quality of zinc coating depends almost entirely upon the composition of the solution; zinc sulphate is superior to chloride, but the addition of some other ingredient is required, among the most serviceable of which is aluminum sulphate, but the authors deny that in this case an alloy of aluminum and zinc is deposited. In the electro-deposition of metals for plating purposes they claim that the physical character of the deposit is better in being more compact, uniform and non-crystalline, when thrown out of solution by secondary rather than by primary action; in the solution under question, the aluminum is the more positive ion, which, on liberation, reacts with the zinc sulphate to deposit zinc. Alum is very frequently used in plating solutions, and its value lies in its being a cheap source of aluminum sulphate. When cast iron or iron containing a considerable amount of graphite is cleaned with acid, the graphite is unattacked, and as the iron is dissolved away, more and more comes to the surface, which then becomes an iron surface to which are attached innumerable small particles of graphite; in trying to electroplate this each particle not only refuses to receive a deposit, but protects the iron in its immediate vicinity from receiving it. This shows the necessity of using some other method than the acid alone for preparatory cleaning of cast iron; a cast-iron surface prepared by the sand blast receives its deposit most readily. The shape of the anode is an important factor in zinc plating; it should be designed so as to conform with the shape of the article to be plated, making the distance from the anode to each portion of the cathode as uniform as possible. As a general rule current density at the anode should be lower than at the cathode. To increase the depth of coatings, recourse is frequently had to "striking" solutions; one of its principles is the use in the zinc-plating solution of a metal salt, the metal of which is more electronegative than the zinc, the most satisfactory of such salts being tin chloride, which is added to the solution in small quantities from time to time. Another principle for striking solutions is the use of an electrolyte in which the zinc does not exist to any appreciable extent, as an electropositive ion, and in which it is, therefore, deposited entirely by a secondary reaction; Newman found the following solution very satisfactory: 0.4 pounds of potassium cyanide is dissolved in 1 gallon of distilled water, to which is added as much zinc carbonate as will dissolve; a current density of 14 to 25 ampères per square foot produces an excellent deposit; but the coating is formed slowly, and there is the disadvantage that the substance is very poisonous.

*Calcium Carbide.*—In an article by Pio in the Lond. *Elec.*, August 29th, he says that in Italy the calcium carbide industry is progressing rapidly, and the number of furnaces operated with continuous or polyphase current is continually increasing. It is only since last year that this industry has become profitable in Italy. Since 1896 acetylene has been introduced into commercial use in small villages, and is now being applied on railways for train lighting. Another field of application is the acetylene gas motor for small industries, but this class of motor has not yet been sufficiently improved to tempt experimenting on a commercial scale. The price of calcium carbide has been raised lately to $87.50 per ton, as against $50 last year, which seems to be the result of a syndicate which was recently constituted on the Continent. In a recent publication of Memmo the conditions required to render the industry remunerative are stated to be as follows: The price of the plant, including machinery, furnaces and all the necessary supplies, must be not higher than $100 per horse-power installed. A certain ratio between the number of tons of carbide produced and the number of effective horse-power must exist. The capital expended must be amortised in ten years; this corresponds to a sinking fund of $8 per ton, so that, including freight, loss, profits, etc., the price to customers does not exceed $60 per ton. At least 6 per cent. must be paid on the capital invested.

*Furnaces.*—Among the several articles that have appeared recently on electric furnaces is one by Haagn in the *Zeit. f. Elektrochemie,* July 31st; it is a Bunsen Society paper and describes a furnace for laboratory purposes, made by Heraeus. It has the advantage that it contains only 1-6 to 1-10 the weight of platinum, which is required in wire furnaces of equal size and durability; this allows, of course, a great saving; the platinum consist of foil 0.007 millimeter in thickness. The furnace is said to be very easily adjustable by the insertion and variation of a series resistance; it is said to follow exactly any variation of the currents. The tubes on which the platinum foil is mounted are best made of china or glass; magnesia is not suitable for high temperatures, as it then begins to become a good electrolytic conductor and the cathodic products of electrolysis destroy the platinum very quickly. At temperatures of 1,500° similar phenomena take place in the otherwise excellent and very refractory so-called Marquardt mass of the Berlin china factory; the temperature is limited by this phenomenon; he has, however, obtained a temperature of 1,700° for a short time, but the china then gets soft. The best form of the furnace is a tube, which is not too wide and not too short. The furnace can be made for any voltage up to 220; lower voltages are better for very high temperatures. In the discussion Heraeus said that he has succeeded in making a non-electrical furnace in which temperatures up to 2,200° can be produced; he uses for this purpose an iridium tube which is suitably placed in a lime furnace, and is heated by means of an oxy-hydrogen flame. The temperature was measured by means of a thermocell, consisting of wire of absolutely pure iridium and an alloy of 90 per cent. of iridium with 10 per cent. of ruthenium. This cell was compared up to 1,650° with a thermocell calibrated by the Reichsanstalt, and the higher values were "calculated."

On the subject of making steel there were two articles; in one by Seidener, published in the *Zeit. f. Elek.*, August 24th, the plant in Gysingen, Sweden, is described. When two years ago the first electric furnace was installed, it yielded 575 pounds in twenty-four hours with 78 kw.; it was used for experimental purposes, but now a larger furnace has been built, and it is claimed that with a 300 horse-power turbine, directly coupled with a generator, this new furnace will give 1,500 tons per year, which means that 72 horse-power give one ton per day. In other electric furnaces it is said that 50 or even 30 horse-power will give one ton of steel per day. It is suggested to use the wasted gases of blast furnaces to drive gas engines, and, if the power cannot be used otherwise, to utilize it in electric-steel furnaces.

The other is a note in the Lond. *Elec.*, September 5th, which states that the possibilities of the electric furnace as a rival of the blast furnace, for the smelting of iron ores, are now being tested at several places in Europe. The Stassano process has been under trial in a plant of 1,500 horse-power capacity at Darfo, in Northern Italy. After inspecting these

furnaces in operation about a year ago, Dr. Goldschmidt, of Essen, reported favorably on their prospects. But the capital available for these experimental trials has now been exhausted, and it was announced in January that the company owning the Darfo plant was in liquidation. From figures published by those financially interested in the Stassano process in 1899, it appears that 2.7 horse-power hours were expected to yield one kg. steel in the electric furnace, and that a saving of $7 per ton of steel was estimated as compared with the cost by the ordinary smelting process in Italy. Whether the liquidation of the company is due to the failure of the Stassano process to attain these results, or is simply due to a shortness of working capital, is not known. Similar trials of the electric furnace for the reduction of iron ores are being conducted at Prague in Austria, at Le Praz in France, and at Gysingen in Sweden, as noticed in the paragraph above, and at the latter place 1,200 kg. steel are said to be produced per day by the Kjellin process. If steel of good quality can be produced in a single operation by the electric furnace from iron ores of average composition, these new processes of ore reduction may have an important future.

*Chlorine and Soda.*—Although this is an important electrochemical industry, little has appeared in the press lately. Glaser gives an account, in the *Zeit. f. Elektrochemie*, August 7th, of an investigation of the Solvay-Kellner mercury cathode process on a laboratory scale, the chief results of which were that a low ampère hour efficiency is due chiefly to the depolarizing action of the chlorine on the alkali amalgam, and that the decomposition of the water is of less importance. Also that without a diaphragm a good efficiency can be obtained only at high-current densities, but with specially prepared diaphragms the efficiency is good at lower-current densities also. J. B. C. Kershaw begins an illustrated article on chlorates in the *Elec. Rev.*, October 4th. After some introductory notes on the reactions and their equations, he describes the Gall and Montlauer and the Carlson chlorate cells.

*Purification of Water by Ozone.*—There is an illustrated description in the *Sc. Am. Sup.*, August 23d, of the Siemens & Halske experimental plant for purifying water by ozone near Berlin.

## THEORETICAL AND EXPERIMENTAL.

*Faraday's Law.*—Fortunately for electrochemists this law, which is the foundation of the whole science of electrolysis, has successfully withstood all attacks made on it, even though at first sight it sometimes appears to fail. Nevertheless further proofs of its accuracy, such as those given in a recent A. A. A. S. paper by T. W. Richards, abstracted briefly in *Science*, August 22d, are always of interest, especially as he finds that the law applies to aqueous solutions and for ordinary temperatures. He reviews his researches in co-operation with Collins and Heimrod, and describes some more recent work done with the assistance of Stull. The weight of silver deposited in the "porous cup voltameter" of Richards and Heimrod, was compared with the weight deposited by the same number of coulombs from a solution of argentic nitrate in fused sodic and potassic nitrates at 300°. After making some corrections and subtracting the weights of alkaline nitrates included in the silver crystals, it was found that the weights were identical within the limits of error of the experiment, namely, about 0.005 per cent. This investigation places Faraday's law among the most exact and invariable of the laws of nature.

*Faraday's Law and Salt Vapors.*—That Faraday's law applies also to vapors is shown by Wilson in some experiments in which he passed electricity through flames containing salt vapors, an account of which may be found in the *Phil. Mag.* for August. Former experiments had shown conclusively that conduction through salt vapors is accomplished by means of ions of some kind and is therefore to this extent at least analogous to conductions through solutions. However, determinations of the velocities of the various ions in salt vapors show that the ions generally behave as if they were much heavier than single atoms, and that the positive ion always moves more slowly than the negative. The experiments described in the present paper show conclusively that above 1,300° C. there is a very close analogy between salt vapors and liquid electrolytes; Faraday's laws of electrolysis are strictly applicable to salt vapors. It is probable that the gaseous ions attract neutral molecules to themselves, which accounts for their small velocities; and apparently the positive ions condense many more molecules in this way than the negative, the latter, therefore, move much the faster. But this condensation, which appears to be peculiar to ions in the gaseous state, need not affect the number of ions produced by the dissociation of one salt molecule or the charges which they carry. He shows that a salt in the state of vapor gives rise to the same number of ions carrying the same charges as a salt in an aqueous solution; or, in other words, the capacity of a salt vapor for transporting electricity is the same as the capacity of an equal amount of salt in the state of solution. He describes in detail the arrangement of his experiments and gives curves showing how the current with a constant e. m. f. of 840 volts, varies with the temperature when solutions of one gram in a litre are sprayed. In each case the current at first rises rapidly to a nearly constant value, which is maintained over a wider or shorter range of temperature. On approaching 1,200° the current again begins to rise rapidly, and somewhere above 1,300° it suddenly attains a nearly constant value. This nearly constant value seems to represent the maximum current which the amount of salt passing through the tube can carry, for it is affected very little by increasing either the temperature or the e. m. f. This current he calls the "saturation" current for the particular salt used. The values of this maximum current are given for various salts in a table. From this table it appears that the maximum current of electricity transported by a salt vapor is proportional to the amount of salt passing between the electrodes, and that the saturation current with a definite amount of any salt passing between the electrodes is inversely as the chemical equivalent of the salt. This amounts to a proof that Faraday's laws of electrolysis apply also to the saturation current carried by a salt vapor. The amount of salt per second of unity electrochemical equivalent which would correspond to a current of 1 ampere, is 0.0101 milligram. Now, 1 ampère second liberates in electrolysis 0.0104 milligram of hydrogen, so that it appears that the factor of proportionality is nearly the same for salt vapors as for electrolytes.

*Unipolar Currents.*—A peculiar apparent departure from Ohm's law was observed by Christiansen in certain electrolytes, and is described in a paper in the *Ann. d Phys.* No. 8, an abstract of which may be found in the *Lond Elec.*, August 8th. He applies the term unipolar current to the current through mercurous nitrate in nitric acid, with mercury electrodes, because this current greatly depends upon the size of the cathode, but not on the size of the anode. The irregularity observed is, that under certain conditions the current is independent of the e. m. f. The nitric acid alone begins to be electrolyzed at 1.7 volts. The mercurous nitrate acid as a depolarizer, and is electrolyzed even at the smallest voltage, but after some time hydrogen is also evolved, giving a counter e. m. f. When the applied e. m. f. is increased, the counter e. m. f. also increases, and it appears that the difference of applied and counter e. m. f. remains constant up to 1.7 applied volts, and hence the current is independent of the e. m. f. It varies, however, directly as the surface of the cathode and as the percentage of mercurous nitrate.

*A Thermochemical Constant.*—That many curious and important relations exist between the constants of nature has long been suspected, and each discovery of a new one adds greatly to our knowledge of these important values of physical properties, which as a rule must be determined empirically, sometimes with great labor and doubtful accuracy. Any such

connecting links between two sets of apparently independent physical properties, at once give an indication of the accuracy and true values of both, and are a great help in discovering many of nature's secrets in relation to the complicated interconnection of various apparently independent properties. One such constant, for instance, is the product of the atomic weights of elements and their specific heats, and called the atomic heat, which is practically the same for nearly all the elements, and is really the number of calories required to raise 1 gram above 1° Centigrade. Another interesting constant relation of a similar nature has been found recently by F. W. Clarke, as shown in a recent A. A. A. S. paper, abstracted briefly in *Science*, August 22d. From a study of the heats of combination of organic compounds as determined by Thomsen, he finds a constant relation which is identical in value with the neutralization constant of strong acids and bases. Thomsen's data relate to substances burned as gas, with the production of gaseous carbon dioxide and liquid water. By a simple correction applied to the last-named factor all the equations of combustion may be reduced to the gaseous form throughout, under uniform conditions of temperature and pressure. When so adjusted, and by the application of a definite formula, nearly every equation yields the above-mentioned constant. Its average value in 65 cases is 13,773 small calories. From this constant and the original equations, the conclusion is reached that the absolute heat of formation, from gaseous, dissociated atoms of the aliphatic hydrocarbons and their simpler derivatives, is proportional to the number of atomic linkings within the molecule. In this calculation every linking counts as one, and single, double or triple unions between carbon atoms become identical as regards their thermal value. The conclusion is revolutionary, but it satisfies the equations which are otherwise indeterminate. The preliminary paper contains 66 verifications of the new law.

*Pulverization of Metals.*—Under certain circumstances a metallic cathode is disintegrated into an extremely fine powder which colors the solution almost like ink as it floats in it. Haber, who has made extended researches of this phenomenon, published an article in the *Zeit. f. Elektrochemie*, August 7th, in which he shows that it is due to the formation and subsequent disintegration of an alloy. He first makes some theoretical remarks on the potential of alloys in electrolytes, showing that an electrode, consisting of an alloy of two metals, has a certain distinct potential difference against an electrolyte, and this potential difference can be calculated theoretically, when the temperature and the ionic concentration of either the one or the other kind of ion is known; if the one ionic concentration is given, the other one is determined thereby. He makes some applications with reference to experiments of Herschkowitsch and others by himself and Sack. In the second part of his article he gives a general review of the phenomenon of the pulverization of metallic cathodes, a characteristic feature of which is that it takes place without any light or spark phenomenon. There are certain other kinds of pulverization of cathodes, but they do not take place during quiescent electrolysis and they have an intimate connection with electrostatic or electrothermic phenomena; the special case treated by him is a simple, purely electrochemical phenomenon. At a cathode in an alkaline solution, an alloy of the cathode material with the alkali metal is formed electrochemically; it could also be made chemically, and has the property of being decomposed in water with a simultaneous pulverization. This shows that cations, when giving off their charges at the cathode, do not rebound from the cathode, like rubber balls from a stone, but they enter into the cathode and form an alloy; this has long been known to be the case for mercury cathodes, but it is also the case for lead and tin, as is proved by the following: Alloys which pulverize, contain a relatively high percentage of the alkali metal, while those with a lower percentage decompose water quietly, without pulverization, but with a formation of a sponge on the cathodic surface. This formation of a sodium alloy at cathodes of lead and tin, is the intermediate process by which a vivid formation of hydrogen at these cathodes in sodium hydroxide is brought about. Some metals, especially platinum, do not pulverize, but become spongy on the surface; there is a great difference in this case between acids and alkalies; the hydrogen ions, with its high mobility, enter much more easily into the platinum than sodium ions. The essential formation of hydrogen in sodium hydroxide cannot be primary, as otherwise platinum would obtain a spongy surface just as well in alkali as in acid. When a cathodic point of platinum in sulphuric acid gets black, it is a case of the formation of a spongy surface. On the other hand, one should be careful not to consider deposits of impurities as a case of a formation of sponge. Billitzer replies to some critical remarks of Haber, in the *Zeit. f. Elektrochemie*, August 28th.

*Electrolytic Preparation of New Alloys.*—Coehn, in a Bunsen Society paper, shows that ammonium, like sodium, can be deposited on a mercury cathode and then forms an alloy, but the liquid state of mercury cannot be the reason for this deposition and of other metals of high solution tension, as it was impossible to get an ammonium deposit with a cathode of Wood metal; the reason why a deposit on a mercury cathode is possible, he believes, is that an alloy is formed. He then tried to deposit alloys of light and heavy metals from aqueous solutions, not by using a cathode of the heavy metal, but by depositing both metals at the same time from the solution. It has been repeatedly stated that the electrolytic deposition of nickel can be improved when a magnesium salt is added to the solution; the reason has not been clearly understood, but the author believes that it is because an alloy of nickel and magnesium is deposited. Such alloy deposits behave quite differently from deposits of pure nickel; while pure nickel does not adhere firmly, a nickel magnesium alloy does. He has made deposits of both upon sheet iron and polished copper sheets, and found that only the alloy deposits are adhesive, while pure nickel scales off. He tried in the same way to obtain an alloy of aluminum and magnesium, but was not successful. The paper is reprinted in the *Zeit. f. Elektrochemie*, August 14th.

*Cathodic Polarization in Dilute Sulphuric Acid.*—A method for measuring the value of the polarization at cathodes of different materials is described by Tafel in a Bunsen Society paper. It is analagous to Caspari's method of measuring the overvoltage required to develop hydrogen at cathodes of different materials; he determined the potential differences between cathode and electrolyte at which the first development of hydrogen bubbles takes place, and the excess over the potential difference between a hydrogen electrode and normal sulphuric acid was called by him the overvoltage of the respective metal; he found that of the metals investigated lead and mercury in pure sulphuric acid show the highest overvoltage; these are the same metals which Tafel has found to be the only suitable cathode materials for producing certain reductions. But while Caspari used a very small current density, Tafel uses comparatively high ones. He uses a rather large polished platinum anode, dilute sulphuric acid, and a smaller platinized platinum cathode; at a fixed current the e. m. f. has quite a distinct value which remains constant for several hours. He uses as anode a bright platinum pan, filled with sulphuric acid, in which is suspended, in a fixed position, a cylindrical platinized-platinum cathode, ending at the bottom in a half globe. This form of cathode can easily be reproduced in other materials, like lead. The e. m. f. is then measured again, while the same current flows, and the difference of the e. m. f. in the two cases of platinized-platinum and lead cathodes, is the "over polarization" of the lead cathode over the platinum cathode at the given current density, under the supposition that nothing is changed at the anode or in the electrolyte; the latter can be found out by again substituting the platinized platinum for the

lead electrode, when the e. m. f. should have the original value again. He says this method enables one to measure the polarization with an exactness of some thousandths of a volt. The paper is published in the *Zeit. f. Elektrochemie*, August 21st.

*Radio-Activity and the Chemical Atom.*—Although the subject of radio-activity may not properly belong under electrochemistry, there is a conclusion drawn in a recent long paper by Rutherford and Soddy in the *Phil. Mag.* for September, which may be of some interest here. They made a detailed investigation of the radio-activity of thorium compounds and found it to be accompanied by chemical changes in which new types of matter were being produced. They conclude that radio-activity is a manifestation of "subatomic chemical change," and the hope is expressed that radio-activity "affords the means of obtaining information of the processes occurring within the chemical atom, in the same way as the rotation of the plane of polarization and other physical properties have been used in chemistry for the investigation of the course of molecular change."

*Positive Electrons.*—A long series of experiments have been made by W. Wien, in which discharges in vacuum tubes were made with perforated cathodes; the positive electrons which travel towards the cathode pass through its perforations and can then be investigated in the same way as the negative electrons in cathode rays, etc. The results which he obtained concerning positive electrons, differ greatly from those formerly obtained for negative electrons, and he believes that certain differences in the color of the fluorescence produced make it possible that chemical influences take part in the phenomenon. For further information see the *Zeit. f. Elektrochemie*, August 14th.

*Electrolysis of Alkaline Chlorides with Platinized-Platinum Anodes.*—It has been known for some time that there is a distinct difference in the process of electrolysis, whether bright or platinized-platinum anodes are used, and, moreover, that the special method of platinizing the platinum also has some influence. Foerster and Mueller recently made extended researches of this action, which they published in a Bunsen Society paper which is reprinted in the *Zeit. f. Elektrochemie*, July 31st. They used the method of Lummer and Kurlbaum, and found that the average e. m. f. required for the electrolysis of alkaline chlorides is smaller for platinized-platinum anodes by 0.5 volt than for bright platinum. The formation of the chlorate proceeds about the same, although it starts somewhat later at the platinized anode than at the bright platinum, and the platinizing of the anode is of influence only upon the electrolytic processes preceding the formation of the chlorate. They made a very long investigation of the causes of this influence of the platinizing, and found that in the electrolysis of neutral solutions of alkali chlorides with platinized anode, the development of oxygen and the formation of chlorate depend only in a very small degree on the catalytic action of the platinum black, and must, therefore, be caused essentially by electrolytic action. In a great many experiments they found that the substitution of a platinized-platinum anode for a bright platinum plate of equal size, causes a considerable decrease in the voltage required for an electrolytic process, whether the electrolyte is sulphuric acid or sodium hydroxide or sodium chloride. This difference of voltage is not the same in all cases; at a current density of 0.067 ampères per square centimeter, it is, after 8 ampère hours for sulphuric acid 0.46 volt, after 3 ampère hours for sodium hydroxide 0.755 volt, after 10 ampère hours for chloride of sodium 0.82 volt; furthermore, at a current density of 0.017 ampère square centimeter after 11 ampère hours for sulphuric acid it is 0.308 volt, after 10 ampère hours for sodium hydroxide 0.665 volt, and after 11 ampère hours for sodium chloride 0.75 volt. This difference of voltage between the electrolysis with bright and with platinized-platinum anode depends, therefore, upon the nature of the electrolyte and more or less upon the current density, while with sodium hydroxide and sodium chloride it also changes considerably with the time. The phenomenon is very complicated and the causes do not seem to be clearly understood; the concentration changes at the anode can explain only a very small part of the voltage difference, but it seems that this difference occurs only at the moment when oxygen is developed at the anode. Caspari's overvoltage of oxygen is too small to explain the whole phenomenon, and besides, to call it overvoltage would only be giving a name to the phenomenon without explaining it.

*Hypochlorous Acid.*—On the basis of the measurements of Jakowin on the hydrolysis of chlorine in aqueous solutions, Luther, in the *Zeit. f. Elektrochemie*, August 21st, shows that it is possible to predetermine theoretically the electromotive behavior of hypochlorous acid, and makes some critical remarks on a recent experimental investigation of Mueller on the same subject.

*Velocity of Electrolytic Decomposition of Oxalic Acid.*—Akerberg has found that when a solution of sulphuric acid, containing oxalic acid, is electrolyzed between polished platinum electrodes, the oxalic acid is scarcely decomposed, but that when platinized-platinum electrodes are used it is readily decomposed. He believes that "the decomposition is, therefore, a secondary process, which is catalytically influenced by the platinum black; it is a purely chemical oxidation effected by the electrolytically separated oxygen. In concentrated solution, with low current densities, or at high temperature, the decomposition follows Faraday's law, but in more dilute solution the reaction is carried out by atomic oxygen." A note on his researches will be found in the Lond. *Elec. Eng.*, September 5th.

*Double Anode Process.*—The compound $(NH_4)_2PbCl_4$, may be prepared electrochemically by using simultaneously an anode of carbon and one of lead. This and the general principle of using two different anodes, one soluble and the other inert, which can be done to advantage for many purposes, are described by Elbs in the *Zeit. f. Elektrochemie*, July 31st.

*Cuprous Ions.*—The chemistry of cuprous compounds is discussed by Bodlaender in the *Zeit. f. Elektrochemie*, July 31st. Among other things he found that the cuprous ions are monatomic, not di-atomic.

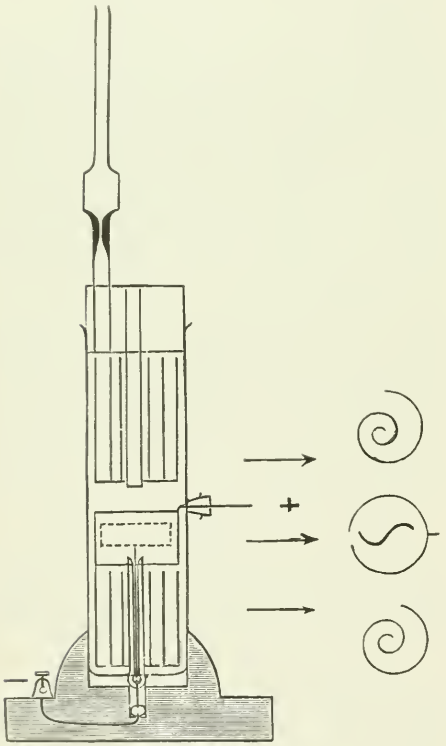
## PRIMARY AND SECONDARY BATTERIES.

*Accumulator Testing.*—The recent literature on batteries seems to be limited to the publication in the *Zeit. f. Elektrochemie*, August 21st, of the complete paper of Liebenow on the use of a third auxiliary electrode in accumulator testing, an abstract of which was noticed in this *Synopsis* last month.

## GENERAL AND MISCELLANEOUS.

*Silver Voltameter.*—The silver voltameter, with all its faults, must be considered a standard instrument until something better has been devised, and meanwhile any of the much needed improvements in it will be welcomed. In a modification described, with illustrations, by Farup in the *Zeit. f. Elektrochemie*, August 14th, apparently with the endorsement of Nernst, the process of weighing is simplified without sacrifice of accuracy; it is claimed to be even more accurate for very small currents. The solution consists of about 10 grams of silver nitrate, with about 15 of cyanide of sodium, dissolved to make 100 c. c. of solution, but with this electrolyte it is absolutely necessary to carefully exclude the oxygen of the air, for if it gains to the silver plate it will dissolve considerable of it. The principle of his apparatus consists in keeping the oxygen away from the platinum cathode by means of properly-arranged shields of silver. The adjoining diagram explains the arrangement. A glass tube, forming the vessel, is provided at the bottom with a platinum wire, which is melted through it and leads to a capillary tube, by which the corrugated platinum cathode is supported. The anode is a sheet of silver which surrounds the platinum electrode, the

current being lead into it from the side. Above and below the two electrodes sheets of silver in spiral form are provided for removing the oxygen which is originally in the solution, or diffuses into it during the test. In order to diminish this diffusion as much as possible, the glass is so completely filled with solution that when the rubber stopper is put in, the solution enters the pipette tube which is set into the rubber stopper. The lower end of the platinum wire dips into a drop of mercury to make a good contact. In order to remove all the oxygen originally in the electrolyte, it is necessary to fill the voltameter some time before the circuit is closed. At the end of the test, the platinum electrode is weighed without any other care, except to clean it in distilled water and dry it for a few seconds over a flame.



SILVER VOLTAMETER.

*Goldschmidt Process.*—Although this process is not electrochemical, it is of interest here in that aluminum is the fuel. Houllevique, in the *Jour. de Phys.*, May, abstracted in the Lond. *Elec.*, August 8th, describes how he prepared pure iron in this way. He recommends the use of at least 3 kgr. of the mixture of aluminum filings, washed in petroleum essence and dried, and pure sesquioxide of iron, free from sulphur and carefully dried, in excess of about 15 per cent. over the amount required for the chemical reaction, and crucibles lined with magnesia. The addition of 20 per cent. of powdered cryolite to the mass increases the fusibility and raises the yield from 30 to 53 per cent. The slightest trace of sulphur is very obnoxious. There is even greater difficulty in obtaining pure aluminum free from fatty matter.

*Magnetic Separation of Zinc Blende.*—The magnetic separation of zinc blende from mixed sulphide ores by means of Wetherill magnetic machines, is now being carried on as a regular process at Denver, Colo., according to the *Eng. and Min. Jour.* for August 16th. The ground product is distributed among eight Wifley tables, which separate it into galena-pyrites and pyrites-blende classes, and the latter are then passed over the two Wetherill machines, each having three magnets. These produce a blende product, assaying about 50 per cent. Zn, 10 to 12 Fe and 1 Pb, which is sold to zinc smelters, while the rest is sold to the lead smelters. One per cent. of iron in the blende makes it susceptible to the intense effect of the Wetherill magnets, while pyrite and galena are not affected. The capacity of the zinc mill at Denver is about 40 to 45 tons of crude ore per day.

*Effect of Atmosphere on Aluminum Alloys.*—Wilson, in a British Association paper, describes tests of the electrical conductivity of certain aluminum alloys as affected by exposure to the London atmosphere. The specimens are in the form of wire, 0.126 in (3.2 mm) diameter, supported on a wooden frame; they were exposed on the roof of a building for thirteen months. The position of aluminum in the electrochemical series with respect to the other substances in the analysis is as follows: Al, Mn, Zn, Fe, Ni, Cu, Si. Copper produces corrosion, which increases with its percentage. Nickel alone has considerable effect, but if alloyed with copper the conductivity slightly increased during exposures. The results of the analysis of the different experiments before and after exposure are given in a table. For exposed-light-aluminum alloys it appears that copper should not be used alone; the presence of equal amounts (about 1 per cent.) of nickel and copper certainly reduces conductivity to a small extent, but the gain in mechanical properties and in resistance to corrosion are great. For further details see Lond. *Elec.*, September 19th.

*Electro Analysis.*—In the *Zeit. f. Elektrochemie,* June 19th, Hanaman gives an illustrated description of an apparatus for this purpose, in which all the different devices and accessories are combined.

The methods of Bindschedler for the electrolytic estimation of mercury, that of Brunck for the estimation of bismuth, and that of Moltke-Hansen for the separation of lead and manganese, are described by Arth in *L'Eclairage Elec.*, August 2d.

*Course in Physical Chemistry.*—The course at the University of Bonn is described with illustrations by Loeb and Rimbach in the *Zeit. f. Elektrochemie,* July 10th.

## CURRENT NOTES.

**American Electrochemical Society.**—The next meeting of the American Electrochemical Society will probably be held in New York City in the spring of 1903; this will be the annual business meeting, with election of officers, etc. We understand that it has been suggested to hold, in the summer of 1903, a joint meeting with the American Institute of Electrical Engineers, at a place near Sault Ste. Marie, Ont. The idea has much to be recommended, but no official steps have yet been taken. From another side it has been suggested that a joint meeting of the American Chemical Society and of the American Electrochemical Society should be arranged. There is no doubt that such meetings would further the interests of electrochemistry, and the social intercourse between electrochemists and their colleagues from the purely electrical and the purely chemical profession would be of value to all concerned. We hope, therefore, that these suggestions which have so far been made only by individual members will be received with favor by the councils of the three societies, and that they may be carried into effect.

**American Aluminum Association.**—The second annual meeting of the American Aluminum Association was held at Pittsburg, Pa., September 18th, 19th and 20th. More than 90 per cent. of the entire aluminum interests of America were represented by delegates. Matters of business relating to the improvement of trade conditions were discussed. A paper on the future of aluminum industry was presented by Dr. Joseph W. Richards. Officers for the ensuing year were elected, Mr. Joseph A. Steinmetz, of Philadelphia, president; Mr. Wagner, of Sydney, Ohio, vice-president; Mr. Palmer F. Langdon, of New York, secretary and treasurer. Various committees were appointed to formulate trade relations and to insure the proper and correct application of the metal to approved uses. It was determined to be represented at the Louisiana Purchase Exposition at St. Louis in 1904 by a large and comprehensive associated display, showing the history of the metal from its discovery, its ores, treatment, processes of reduction, and applications of the metal, as well as a complete display of all articles thus far successfully made of aluminum. The Metallurgical Committee, who will have this development in hand, is composed of Dr. Joseph W. Richards, who has been ever identified with aluminum and its history and metallurgy; Mr. Arthur V. Davis, general manager of the Pittsburg Reduction Co., the largest producing company of aluminum in the world, and Mr. Joseph A. Steinmetz, who has been for some ten years closely associated with the metal and its fabrication and general application in the arts and sciences.

**Mineral Products of the United States.**—The United States Geological Survey has published a very interesting statistical table showing the mineral outputs of the United States in the ten years, 1892 to 1901. Among the metallic products we find aluminum, the output of which in 1892 was 259,885 pounds, with a value of $172,824, and in 1901, 7,150,000 pounds, with a value of $2,238,000; that is, the output of aluminum in 1901 was more than 27 times greater than in 1892, while the value per pound in 1901 was less than one-half of that of 1892. At the end of this table interesting statistics of the total value of the mineral products since 1880 are given: $369,319,000 in 1880; $619,648,925 in 1890, and $1,092,224,380 in 1901. The table has been compiled by Director Charles D. Walcott, under the supervision of Dr. David T. Day.

## CORRESPONDENCE.

### THE ELECTROMOTIVE FORCE OF THE DANIELL CELL

*To the Editor of the Electrochemical Industry:*

Sir:—Professor Carhart is quoted in your September issue, page 9, in his "Contributions to the Theory of Concentration Cells," as saying that the increase of the electromotive force of the Daniell cell with the increase of density of the copper sulphate solution, and its decrease with increase of density of the zinc sulphate solution, is clearly explained by his thermo-electric theory, and that "the only other explanation of this fact ever given is based on osmotic pressure."

Without going into any criticism of the thermo-electric theory of concentration cells (which theory the writer is not yet ready to accept as explaining the *origin* of their electromotive force), the writer wishes to call attention to the fact that another explanation of the Daniell cell phenomenon is to be found, which is based neither on a thermo-electric theory, nor on the theory of osmotic pressure, but on a few well-demonstrated *experimental facts.*

We all agree that the difference in the heats of formation of zinc sulphate and copper sulphate, in aqueous solution, is the chief, if not the only, source of the electromotive force of the cell in question. But, these heats of formation vary with the concentrations of the solutions formed, both of them increase as the solutions formed are the more dilute. Therefore, if the copper is deposited from a more concentrated solution, in which the formation heat of the copper salt is less, the value of the heat energy transformed in the cell is increased, and its electromotive force correspondingly *increased.* If, on the other hand, the zinc is dissolved into a more concentrated solution, the formation heat of the zinc salt is less, and the electromotive force of the combination is correspondingly *decreased.*

Similar thermochemical considerations, of the varying solution heats of sulphuric acid of varying dilutions, are applicable to explain part of the variations of electromotive force of the lead accumulator.

These thermochemical data are such well-established facts, and their applicability to explain the variations in the Daniell cell referred to, as well as to concentration cells in general, so patent and necessary, that it seems that the statement of Prof. Carhart must be revised so as to take these into account.

Joseph W. Richards.

Lehigh University.

## BOOK REVIEWS.

Monographien über Angewandte Elektrochemie. I. Band: Die Elektrolyse des Wassers. Von Viktor Engelhardt. Halle: Wilhelm Knapp, 1902. 117 pages, with 90 illustrations and 15 tables. Price, 5 marks.

This is the first volume of a series of monographs, to be published at regular intervals on special subjects of applied electrochemistry. Each volume is to give a full and detailed report of the development and present state of the subject treated in it. Viktor Engelhardt, the chief chemist of the Siemens & Halske Co. in Vienna, will be the editor of the whole series. He is also the author of the first volume which deals with the electrolysis of water, its methods and its use.

The author first gives some historical notes on early investigations, and notices the physical and chemical constants which enter into the problem. He then describes in detail and at length the different methods which have been devised for the electrolysis of water. The methods for producing oxygen and hydrogen separately are divided into three classes. In the first one porous diaphragms of non-conducting material are used; in this class are the processes of d'Arsonval, Latchinoff, Ducretet, Renard, Delmard, Bell, Schmidt. In the second class solid, non-porous and non-conducting diaphragms are used which, of course, do not separate the whole electrolyte into entirely separate parts, as globes or bells of non-conducting material are placed around the electrodes. Here we have some well-known laboratory apparatus, and also the methods of Ascherl, Schoop, Hazard-Flamard, Verney. The third class is similar to the second, but conducting non-porous diaphragms are used and the e. m. f. is kept low enough to prevent a diaphragm from acting as cathode on one side and as anode on the other side. In this class are described the methods of Garuti, Siemens Bros. and Obach, Schuckert & Co. All these methods are described in detail with many illustrations. The author then describes the various voltameters in which oxygen and hydrogen are produced together, and notices the attempts which have been made to obtain pure oxygen by electrolysis without the use of diaphragms; this may, for instance, be done by using a depolarizing cathode which is reduced during electrolysis. This chapter is concluded by a table which gives a good review of the different patented processes and their particular features.

In the second half of the book the author discusses the commercial aspect of the problem and the commercial use of the products of the electrolysis of water. He gives data on the cost of the gases when produced by the different processes and then discusses the following commercial applications: oxygen and hydrogen together for producing high temperatures, for lighting, for blasting; hydrogen for filling balloons, for soldering and for lighting. The book is concluded by an appendix containing several tables, and by an index giving the names of authors and inventors.

The Copper Handbook. Vol. II. Compiled and published by Horace J. Stevens, Houghton, Mich. Paper, $1; buckram, $2; full morocco, $3.

This handbook is designed chiefly for business men and others who are financially interested in copper mines.

For such, as well as for the general scientific public, the book is valuable, for in it are compiled many facts about the history, metallurgy, mining and uses of copper.

Almost every mine in the world receives a short notice, and the great mines of Montana, Arizona and Michigan are the subject of short historical sketches. As the information on which these sketches are based is semi-official, it can be scarcely doubted that it is fairly reliable. But the outputs of some of the smaller mines is rather an estimate of what might be done under most favorable conditions than a statement of past production.

The chapter on general copper statistics is especially valuable, and contains many useful tables, as, for instance, a table converting London price of copper expressed in pounds sterling per long ton, to cents per pound—the American units. In this connection, it is well to note that there are four tons used in weighing copper and its ores. Troy, avoirdupois, metric and long tons. This certainly throws a burden on the statistician of copper.

For the class for which this book is written the book certainly is a useful compendium and a handy book to have near at hand.

## BOOKS RECEIVED.

Monographien ueber angewandte Elektrochemie. Vol. II. Die Gewinnung des Aluminiums. By Adolphe Minet Translated into German by Dr. Emil Abel. Halle: Wilhelm Knapp. 129 pages, with 57 illustrations and 15 tables. Price, marks 7.

Monographien ueber angewandte Electrochemie. Vol. III. Die Darstellung des Chroms und seiner Verbindungen mit Hilfe des elektrischen Stromes. By Dr. Max LeBlanc. Halle: Wilhelm Knapp. 110 pages. Price, marks 6.

Einfuehrung in die Elektrochemie. Nach der elektrolytischen Dissociatiationstheorie. By Peter Gerdes. Halle: Wilhelm Knapp. 124 pages, with 48 illustrations.

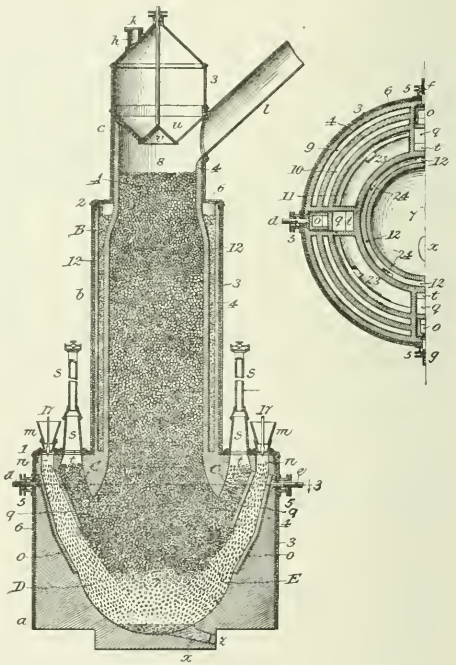
The Mineral Industry. Its Statistics, Technology and Trade in the United States and other countries to the end of 1901. Founded by Richard P. Rothwell. Edited by Joseph Struthers, Ph. D. Vol. X. New York: The Engineering and Mining Journal. 920 pages. Price $5.

The Optical Rotating Power of Organic Substances and Its Practical Applications. By Dr. Hans Landolt, assisted by Dr. O. Schoenrock, Dr. P. Lindner, Dr. F. Schuett, Dr. L. Berndt and Dr. T. Posner. Second edition. Authorized English translation with additions by Dr. John H. Long. 751 pages with many illustrations. Easton, Pa.: The Chemical Publishing Co. Price, bound in cloth, $7.50.

## A CLOSED CONTINUOUS-WORKING ELECTRIC FURNACE.

The adjoining illustrations represent a type of electric furnace invented by E. R. Taylor, Penn Yan, N. Y., and primarily intended and used at present for the manufacture of carbon bisulphide. The principle of this latest type permits, however, a much wider application and the inventor states that he will soon apply it to the manufacture of other chemicals.

One of the distinguishing features in the latest type is the electrodes, which are self-renewing and feed themselves by gravity. As shown in the cut the furnace is vertical shaped, and on the inside at the bottom is rounded. The inlet pipees are designated by *mm*, *ss* and *h*. There are the sources of current at *d* and *e*, and connected to them on the inside are trough-shaped conduits which extend towards the bottom of the furnace. The lower part of the conduits are constructed at an angle so that the descent of the fragmentary matter is retarded and thrown inwardly towards the middle of the working chamber, where the heat zone is. The electrodes, feeding themselves by gravity, descend into the bottom of the working chamber from the outlet of the conduits *o*, and gradually come close together at the bottom. They are naturally thinnest where they come together, thus affording the necessary resistance, and converting the electricity into heat. The heat zone is thus located at the bottom. There are four



TAYLOR ELECTRIC FURNACE.

electrodes, which are diametrically opposite each other, and are situated 90° from each other.

The fragmentary carbon is introduced at *ss* or at *h*, and the crushed sulphur at *mm* and corresponding points around the furnace. The sulphur is thrown towards the bottom of the working chamber and thus it is fused at the same time with the carbon. The vapors ascend up through the furnace through the pipe 1 into condensers, and are there liquefied. At the bottom of the furnace is a tap-hole *x*, where the residue may be taken out.

The furnace is continual in its operation, and at no time does the current have to be shut off to insert fresh material.

The manufacture of carbon bisulphide is carried on extensively at this plant, and there is a good market for it. Carbon bisulphide is used in large quantities for exterminating the insects and small animals which destroy thousands of dollars' worth of grain annually; for this purpose no exterminator is said to have given as much satisfaction as carbon bisulphide. It is also used for other purposes, among which may be mentioned the following: As a disinfectant; for preserving perish-

able articles; with chloride of sulphur for vulcanizing india rubber; for extracting oil from seeds, wool, bones, etc. Carbon bisulphide evaporates quickly, and the fumes, which are heavy, descend into the grain, cracks and holes, and effectually destroy all animal life. Attention has recently been called to important new applications in London *Engineering*, where, it is said, that the economy of cyanide recovery processes in coal-gas manufacture is threatened by a new process depending on the use for the same purpose of carbon bisulphide.

## A NEW STORAGE BATTERY.

An interesting cerium storage battery has recently been devised by Dr. Auer von Welsbach, the famous Austrian chemist and inventor of the incandescent gas-light mantle and of the osmium electric incandescent lamp. It may be called a cerium battery because it is the use of cerium salts which is its peculiar novel feature. To characterize the cell in a general way, it may be said to be of the type of the Bunsen battery. It is a double fluid cell with diaphragm. The positive plate (the plate where the current leaves the cell during discharge) is inert; the negative plate is amalgamated zinc; the electrolyte at the negative plate is

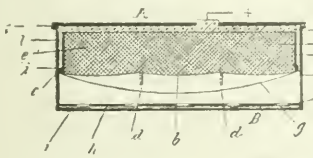


FIG. 1.—WELSBACH STORAGE BATTERY.

zinc sulphate. So far is the construction the same as that of the Bunsen cell. But while in the latter strong nitric acid is used as the depolarizer at the positive plate, Auer von Welsbach uses a specially prepared saturated solution of a double salt of sulphates of cerium and zinc; as positive plate he uses a finely divided fabric of elastic graphitized carbon. During discharge zinc dissolves and ceric sulphate is reduced to cerous sulphate. During charge zinc is deposited upon the electrode, and at the other end cerous sulphate is oxidized to ceric sulphate.

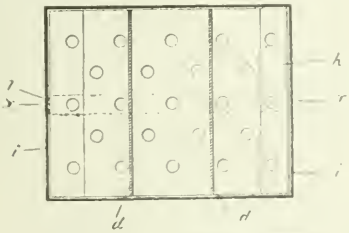

FIG. 2.—WELSBACH STORAGE BATTERY.

The construction of the battery is shown in the adjoining diagrams. Fig. 1 shows a vertical section, Fig. 2 a horizontal section. The negative plate is a perforated sheet of amalgamated zinc *h*, 1 mm. thick, covered with mercury; it is in contact with the amalgamated iron strip *l*. The positive electrode consists of a fabric or of foils of elastic graphitized carbon *e*, which is contained in a celluloid frame *c*, which is open at the upper and at the lower side. At the upper side a graphite plate *f* is pressed slightly against the fine graphite fabric—*d* and *d* are small cross pieces which hold the graphite fabric in position. At the lower rim of the celluloid frame the arched diaphragm *g* is attached; it has to prevent any pieces of carbon from falling down upon the zinc plate; it also prevents mixing of the electrolytes, and causes any bubbles of hydrogen gas which arise, to escape upwards along the sides.

To set up the battery, the celluloid frame containing the graphite fabric is placed into the box containing the negative plate; the upper part with the graphite fabric is then filled with the cerium electrolyte. If the battery is used for stationary purposes, stirring is necessary. For service on automobiles it is claimed that the vibrations of the carriage are sufficient. The cell is said to be best adapted to purposes when the discharge follows the charge immediately.

The e. m. f. of the battery is claimed to be higher than that of the lead accumulator, the capacity, per unit of weight, is said to be several times that of the lead accumulator.

## PERSONAL.

The following is the complete alphabetical list of the members and guests who registered at the Niagara Falls meeting of the American Electrochemical Society:

E. G. Acheson, Chas. E. Acker, Niagara Falls, N. Y.; W. D. Bancroft, Ithaca, N. Y.; H. T. Barnes, Montreal, Que.; Chas. B. Barton, Berlin, N. H.; Mrs. J. Warner Batt, Albany, N. Y.; Geo. H. Baynes, Jr., Ithaca, N. Y.; F. M. Becket, Niagara Falls, N. Y.; C. H. Benjamin, Buffalo, N. Y.; H. S. Blackmore, Mt. Vernon, N. Y.; Earl Bogue, Ithaca, N. Y.; Chas. S. Bradley, Geo. F. Brindley, Niagara Falls, N. Y.; Oliver W. Brown, Bloomington, Ind.; Wm. Hand Browne, Jr., New York City; C. F. Burgess, Madison, Wis.; Miss Burnell, Charlotte, N. C.; Eugene A. Byrnes, Washington, D. C.; Henry S. Carhart, Ann Arbor, Mich.; H. R. Carveth, Ithaca, N. Y.; H. B. Cho, New York City; Chas. W. Coit, C. A. Collins, Jr., Niagara Falls, N. Y. Miss L. Conord, Miss A. Conord, West Hoboken, N. J.; Alfred H. Cowles, Cleveland, Ohio; G. E. Cox, Niagara Falls, N. Y.; F. B. Crocker, New York City; E. A. Deeds, Niagara Falls, N. Y.; L. C. Dodd, Buffalo, N. Y.; Norman Dodge, Philadelphia, Pa.; W. F. Doerflinger, Niagara Falls, N. Y.; C. S. Doggett, E. Chicago, Ind.; Sarah R. A. Dolley, Rochester, N. Y.; Wm. H. Dopp, Buffalo, N. Y.; Chas. A. Doremus, Gustav Drobegg, New York City, Henry H. Durham, G. W. England, R. W. England, Buffalo, N. Y.; Francis A. J. Fitzgerald, Niagara Falls, N. Y.; L. H. Flanders, Pittsburg, Pa., Geo. W. Fletcher, Brooklyn, N. Y.; Francis Forbes, New York City, S. P. Franchot, Niagara Falls, N. Y.; Oliver P. Fritts, Denver, Colo., Austin Fritchle, Mrs. Austin Fritchle, Tuskaloosa, Ala.; Wm. C. Geer, Ithaca, N. Y.; A. E. Gibbs, W. T. Gibbs, Niagara Falls, N. Y., W. E. Goldsborough, St. Louis, Mo., Chas. J. Greenstreet, Coal City, Pa., F. Haber, Karlsruhe, Germany, Max M. Haff, C. M. Hall, S. F. Hall, Niagara Falls, N. Y.; C. Hanbuechen, Madison, Wis.; Wm. D. Harris, Philadelphia, Pa., Edward Hart, Easton, Pa., Walter H. Hart, Philadelphia, Pa.; J. C. Hecklau, Buffalo, N. Y., Carl Hering, Philadelphia, Pa.; Aldus C. Higgins, Worcester, Mass.; Wm. H. Hoskins, Chicago, Ill., G. M. Howard, Philadelphia, Pa.; Henry Howard, Brookline, Mass., R. S. Hutton, Manchester, Eng., Alois von Isakovics, New York City, Geo. N. Jepson, Worcester, Mass., Woolsey McA. Johnson, New Brighton, N. Y.; Louis K. Kimberg, Madison, Wis.; N. S. Keith, New York City, R. N. Kefid, Buffalo, N. Y., A. S. Krebs, Washington, D. C.; A. A. Knudson, New York City, H. S. Lamdale, Buffalo, N. Y.; A. B. Lambert, Great Works, Me.; Miss C. A. Lee, Rochester, N. Y.; P. M. Lyon, Pittsburg, Pa.; C. F. Lyon, Iowa City, Iowa, D. R. Lyon, Niagara Falls, N. Y., F. J. Mackie, Chicago, Ill.; Albert Marsh, Niagara Falls, N. Y., A. B. Martin, Jr., Washington, D. C.; Wm. O. Mathews, Miss W. O. Mathews, Cleveland, Ohio; F. G. Maxwell, Brooklyn, N. Y.; James J. McComas, Coldwater, Pa.; J. A. McKittrick, Schenectady, N. Y., James McMahon, Niagara Falls, N. Y.; Jas. A. Miller, Buffalo, N. Y., W. J. Moore, Toronto, Ont.; Max Moore, Niagara Falls, N. Y.; Russell F. Morgan, Buffalo, N. Y.; Henry G. Morris, Philadelphia, Pa.; H. B. Morse, Buffalo, N. Y., E. H. Morse, New York City, R. J. Nolan, Schenectady, N. Y., E. M. Olcott, Philadelphia, Pa., J. G. O'Neil, Niagara Falls, N. Y.; J. A. Parsons, Baltimore, Md., Geo. W. Patterson, Ann Arbor, Mich., C. L. Peirce, Niagara, N. Y., Frank C. Perkins, Buffalo, N. Y., Joseph Perkins, Cleveland, Ohio, Herbert W. Pike, Philadelphia, Pa., Henry Nott Potter, New York City, E. F. Price, Niagara Falls, N. Y., S. Reed, Washington, D. C.; C. L. Reed, Indianapolis, Ind., Arno Reichenstahl, Miss Arvil Reuter, Pittsburg, R. I. Jones, W. Richards, Wm. Richards, Bethlehem, Pa.; W. A. Robbins, Miss W. A. Robbins, Camden, N. J., J. C. Roberts, A. G. Rogers, Niagara Falls, N. Y., Hugh Rogers, E. F. Roeber, C. W. Rogers, Indianapolis, Ind., E. R. Roseberg, Troy, N. Y., S. H. Ross, E. G. Spink, Philadelphia, Pa., Bertram E. Sanborn, Boston, Mass., F. E. Schermerhorn, New York City, Geo. O. Seaton, Hampton Roads, Va., Samuel Sheldon, Brooklyn, N. Y., E. S. Shumway, Ithaca, N. Y., John L. Smith, Niagara Falls, N. Y., A. W. Smith, Cleveland, Ohio, Edward W. Smith, Philadelphia, Pa.; W. O. Snelling, Washington, D. C., C. C. Sneden, New York City, Elmer A. Sperry, Mrs. C. A. Sperry, Cleveland, Ohio; Thos. E.

Steen, Niagara Falls, N. Y.; Thomas G. Steward, Washington, D. C.; Walter P. Taggart, Philadelphia, Pa.; Edward R. Taylor, Miss Edith Taylor, Mrs. E. R. Taylor, Chas. E. Taylor, Penn Yan, N. Y., C. W. Thomas, Mrs. C. W. Thomas, Hutley, N. J.; Geo. H. Thornton, Buffalo, N. Y.; Erik W. Tillberg, Worcester, Mass.; F. J. Tone, Niagara Falls, N. Y.; C. P. Townsend, Washington, D. C.; Geo. M. Turner, Buffalo, N. Y.; W. H. Walker, Boston, Mass.; W. D. Weaver, New York City; A. T. Weightman, Samuel Weil, Niagara Falls, N. Y.; G. G. Wiechmann, Brooklyn, N. Y.; Ray Hill White, R. A. Whitherspan, Niagara Falls, N. Y.; S. E. Whiting, Cambridge, Mass.; W. R. Whitney, Boston, Mass.; Wm. M Whitten, Niagara Falls, N. Y.; Chas. L. Wright, Washington, D. C.; O. G. Victor, Buffalo, N. Y.; H. N. Yates, North Tonawanda, N. Y.

We reproduce herewith a photograph of the foreign guests of the American Electrochemical Society at the Niagara Falls meeting. Prof. F. Haber, of the Institute of Technology, of Karlsruhe, Germany, and Mr. R. S. Hutton, of Owens College,

F. HABER AND R. S. HUTTON.

Manchester, England. We are indebted for this picture to Mr. Walter R. Taggert, of the University of Pennsylvania, who took the snap-shot on the veranda of the International Hotel at Niagara Falls. Mr. Hutton has meanwhile returned to England. Professor Haber is in the West, and will sail for Germany in November.

Mr. Titus Ulke has returned to Sault Ste. Marie from an extended trip to the West.

## OBITUARY.

Sir Frederick Abel died suddenly on September 6th, at his residence in Whitehall Court, London. He has been best known as the chemist to the British War Office, from 1854 to 1888. In this capacity he conducted the researches which led to the adoption of the smokeless powder or cordite. He took great interest in technical education and research, and was also intimately connected with the electrical profession, being in 1877 the president of the British Institution of Electrical Engineers. He also served at various times as president of the Chemical Society, the Institute of Chemistry, the Society of Chemical Industry, and the Iron and Steel Institute, and was a fellow of the Royal Society. Among his numerous writings was a treatise, in 1884, on electricity applied to explosive purposes. He was born in 1827 and entered in 1845 the Royal College of Chemistry, where he obtained his chemical training under the famous German chemist, A. W. von Hofmann.

## INDUSTRIAL NOTES.

Mr. Marcus Ruthenberg, Philadelphia, is said to contemplate installing a very large reduction plant for the Pennsylvania Steel Co.

Mr. J. L. Malm, Marysville, Mont., is installing an electrical precipitation plant in connection with cyaniding operations, the only one in the State of Montana.

A firm in California is said to be introducing an electrolytic-alkali process, the first at the Pacific Coast.

We have received from President A. E. Newton, of the Cutter Electrical and Mfg. Co., Philadelphia, their recently-issued most-handsome book, "ITE Switchboard Practice." It is one of the best examples of the modern type of trade catalogues, print and illustrations being beautiful. The principle of the automatic circuit breaker and its application to all the various purposes for which it may be used are discussed, the descriptions being profusely illustrated. Of special interest to our readers will be the chapter on the use of the circuit breaker in connection with storage batteries. The book also contains chapters on measuring instruments (Keystone instruments) and on switchboard construction.

Water-Power.—The firm of Pepper & Register, Philadelphia engineers and general contractors, are developing a large water-power on the St. Lawrence River, about 18 miles from Ogdensburg, N. Y. The complete hydraulic development is to be installed at once, and the electrical power to be installed in increments when sold to consumers. The total development is for 34,500 mechanical horse-power. The power plant is admirably located. No inland port could have greater advantages for shipping. The region of the Great Lakes, with its resources and enormous trade, and the entire basin of the St. Lawrence are tributary to it, and bring the development in close touch with the chief centers of the American continent. The plans proposed by Pepper & Register are for extensive piers and wharves on the St. Lawrence River. The plans also contemplate excellent railroad connections. By the construction of a short road to Ogdensburg, direct connection is made with the New York Central and Hudson River Railroad, the Grand Trunk Railroad, the Rome, Ogdensburg and Watertown and the Rutland Railroads. The place is admirably suited for electrochemical industries to settle down. The natural advantages for construction of a larger power plant at Waddington are such that the cost of development will be low. Pepper & Register are prepared to make contracts for the sale of power, to be delivered within twelve months, which will be as soon as it would be possible for industrial enterprises to complete their buildings and establishments ready to receive this power.

## DIGEST OF U. S. PATENTS PRIOR TO JULY, 1902.

*Compiled by Byrnes & Townsend, Patent Lawyers, National Union Building, Washington, D. C.*

*This digest of electrochemical United States patents prior to July, 1902, will be one by classes, setting out for comparison in each class those devices which have the same object, or those methods which seek the same results. In each class the patents will be arranged chronologically. The digest will be complete in the sense of covering every point which is touched upon in the original specification.*

ELECTROLYSIS OF SODIUM CHLORIDE WITH MERCURY CATHODES.—(CONCLUDED.)

578,457. March 9, 1897; C. Kellner, Vienna, Austria-Hungary. Mercury cathode flows in helical path under the anode.

Withdrawn into decomposition vessel, where amalgam flows over inclined riffle in ammonium nitrate solution, forming ammonia and caustic soda.

Cathode in this vessel and current generated is used as desired.

Mercury cooled and return.

586,635. July 20, 1897; H. C. F. Stormer, Christiania, Norway.

Amalgam-washing apparatus.

Amalgam lifted in perforated tray and flows down through water over rods of glass, ebonite or carbon.

586,729. July 20, 1897; C. Kellner, Vienna, Austria-Hungary.

Mercury cathode descends in helical or zigzag channel, passing repeatedly through openings in a non-conducting partition, and coming alternately into contact with the electrolyte and the oxidizing solution.

In latter solution is short circuited with metal-containing vessel.

Vertical tubular carbon anode serves as feed tube for sodium chloride in one modification.

588,276. August 17, 1897; C. Kellner, Vienna, Austria-Hungary.

Mercury containing sodium withdrawn from decomposing cells through rocking box to break connections, and passed through a series of oxidizing cells, between which electrical connections are likewise broken.

Each oxidizing cell contains a cathode to which amalgam acts as anode. These cells are electrically connected in series, whereby is obtained a current of potential sufficiently high to be employed in decomposing cells.

600,211. March 8, 1898; H. C. F. Stormer, Christiania, Norway.

Reduces decomposition of water of electrolyte by separated sodium, by gently agitating the mercury cathode, whereby portions of the superposed amalgam film are continuously dissolved by, or diffused throughout, the body of the mercury.

Uses vertically reciprocating perforated plates or horizontally reciprocating riffled plate.

608,300. August 2, 1898; B. E. F. Rhodin, Sault Ste. Marie, Can.

Modification of Rosenbaum's device (546,348).

Mercury cathode in circular cell having radial ribs.

Anodes in circular bell having plurality of open-ended tubes projecting into mercury.

As anode cell revolves, amalgam formed in tubes comes in contact with water in external cell.

614,353. November 15, 1898; H. C. F. Stormer, Christiania, Norway.

Amalgam-washing device; amalgam drawn off into washing vessel, containing a skeleton drum, formed of side discs connected by a series of rods. As drum revolves, amalgam is carried up by rods and exposed in thin film to solvent.

May increase surface by placing open-mesh metal cloth around rods or weaving it through them.

627,193. June 20, 1899; J. F. Kelly, Pittsfield, Mass.

Amalgam-washing device. Amalgam circulates through chamber having carbon sides. Carbon sides, in electrical contact with amalgam, hasten oxidation and do not affect color of caustic.

631,468. August 22, 1889; C. Kellner, Vienna, Austria-Hungary.

Electrode in oxidizing cell, and a short circuit between amalgam and such electrode, such short circuit constituting a part of the return line of the main circuit.

In this construction the current derived from oxidation of the sodium is opposed to main current, and oxidation of mercury is avoided.

630,234. November 7, 1899; E. Baker, Winchester, Mass.

Mercury cathode flows in tortuous channel between low partitions which support the anodes. The discharge pipe is U shaped, and rises outside the cell to such height above the mercury within as will counterbalance the electrolyte, thus forming effective seal.

Oxidizing cell contains relatively deep layer of amalgam, which is thereby permitted to stratify. Flow of lighter amalgam is further retarded by inclined dams, imperforate at top.

645,055. March 13, 1900; H. S. Anderson, Springfield, Mass.

Mercury has tortuous flow in both decomposing and oxidizing cells, but latter is at higher level than former and amalgam is forced up by centrifugal pump. The barrel of this pump is perforated at such level that, in case pump works too rapidly, mercury will overflow, but electrolyte will not be pumped into oxidizing cell.

646,313. March 27, 1900; B. E. F. Rhodin, Sault Ste. Marie, Can.

Apparatus generally similar to 608,300, except that anode tubes are closed at upper end by inclined diaphragms, and anodes consist of crude copper in sodium sulphate solution.

Copper sulphate formed in anode compartment and sodium amalgam at cathode.

Ribs under mercury are inclined to radii, whereby the motion of anode bell causes amalgam to work outward toward periphery. After oxidation occurs the heavier mercury flows back toward center and under anodes.

652,761. July 3, 1900; J. B. Entz, Philadelphia, Pa.

In cell of Castner type affects circulations of the mercury by means of magnetic field.

659,655. October 16, 1900; E. Edser, London, Eng.

Cell divided into two or more compartments by one or more vertical partitions consisting of superposed V-shaped troughs of glass, or metal partly covered with mica, each trough containing sufficient mercury to cover the lower edge of the trough above. Brine electrolyzed in one compartment by a current passing from a carbon anode to the mercury in the troughs. The deposited sodium diffuses through the mercury to the other side of the partition, where it is oxidized by water, which fills the second compartment. The electrolyzing compartment is covered by a removable hood with outlet for chlorine, the lower edge of which extends into a mercury seal, a layer of vaseline or oil on the mercury protecting it from chlorine. To facilitate oxidation of sodium, places iron wire-gauze cathode in water compartment, and either short circuits it to mercury in troughs or connects terminals of dynamo to the carbon anode and iron cathode, the mercury acting as a bipolar electrode. In the latter case, interposes a resistance wire between the mercury and iron cathode to direct more current through the brine than the water. The vertical partition may be flat or annular. May employ a horizontal or an inclined partition with troughs of ⌣⌢ section, the lower edge of each dipping into mercury held in the next.

661,188. November 6, 1900; A. Nettl, Prague, Austria.

Cathode consists of a number of fine streams of mercury, flowing through holes or nozzles in the bottom of a supply vessel down through the brine, between carbon anodes. The sodium amalgam collecting at the bottom of the cell is protected from the brine by a layer of chloroform or carbon disulphide, lying upon the amalgam. Jets of mercury may be forced through the brine from below, in any desired direction, instead of allowing it to drop vertically.

673,754. May 7, 1901; G. and G. W. Bell, Liverpool, Eng.

General construction that of Castner cell, with two electrolyzing chambers and an intermediate oxidizing chamber. Causes the mercury to reciprocate between the chambers by first closing the chlorine outlet of the electrolyzing chamber, until the pressure of accumulated chlorine, acting on surface of brine, forces amalgam into oxidizing chamber, and, then, after a suitable interval for oxidation, opening chlorine outlet and allowing depleted mercury to flow back. Chlorine outlet may

be automatically controlled by a hydraulic timing device, or an electric motor meter in main circuit, or clockwork. May also force amalgam into oxidizing chamber by automatically raising level of brine in electrolyzing chamber, and then lowering level to permit mercury to flow back.

674,927. May 28, 1901; M. Mauran, Niagara Falls, N. Y.

Cathode for the oxidizing chamber of Castner cell used at Niagara, consisting of a series of parallel wrought-iron bars connected at the ends by cast-lead blocks.

674,930. May 28, 1901; M. Mauran, Niagara Falls, N. Y.

Adjustable knife-edge supports for Castner cell used at Niagara, and ball-and-socket connection to pitman which rocks cell.

674,931 and 674,933. May 28, 1901; M. Mauran, Niagara Falls, N. Y.

Anodes for the Castner cells used at Niagara, consisting of carbon bars having horizontal flanges at each side to extend over the mercury cathode, the flanges being slitted to facilitate escape of chlorine. Terminals consist of copper-plated carbon plugs, driven into recesses in upper portion of anode and connected by zigzag lead strips soldered to plugs. Upper portions of anodes extend through slots in cell cover and are surrounded by Portland cement.

674,932. May 28, 1901; M. Mauran, Niagara Falls, N. Y.

T-shaped pipe for removing gas from tilting Castner cell used at Niagara. Two branches of pipe extend into two gas-producing chambers and the third leads into gas main.

674,934. May 28, 1901; M. Mauran, Niagara Falls, N. Y.

Cathode for oxidizing chamber of Castner cell used at Niagara, consisting of a series of thin, parallel wrought-iron bars, each bent upward at right angles at both ends, with the free ends again bent at right angles to give horizontal terminals, which extend out of the cell.

678,851. July 23, 1901; H. S. Anderson, Springfield, Mass.

Interposes between mercury cathode and bottom of cell a thin, porous layer of pipe clay or pumice stone, which becomes saturated with brine, so that sodium is deposited on lower as well as upper surface of mercury. Porous layer may have a ridge extending into brine, with vertical openings to facilitate passage of brine into portions beneath mercury.

679,476. July 30, 1901; J. F. Kelly, Pittsfield, Mass.

Movable outer vessel contains layer of mercury and water. Electrolyzing chamber consists of fixed box with open bottom, within and extending down into mercury in outer vessel. Outer vessel reciprocated to bring new surfaces of mercury beneath brine and expose amalgam to water.

679,477. July 30, 1901; J. W. Kynaston, Liverpool, Eng.

Cathode consists of thin horizontal layers of mercury held in superposed non-conducting trays. Openings at alternate ends of trays cause mercury fed into upper tray to travel back and forth through series, amalgam escaping from bottom tray. Depth of mercury in each tray determined by a transverse ridge near discharge opening. Terminal wires touch mercury in each tray. Carbon anode may be placed between two vertical sets of trays.

680,440. August 13, 1901; B. E. F. Rhodin, Sault Ste. Marie, Can.

Stationary horizontal pan contains layer of mercury and water. Electrolyzing chamber rotates on vertical axis within pan and consists of a series of radial anode compartments of vitrified earthenware, the sides of which extend down into the mercury. A central cup has radial ducts, which serve to distribute brine into each anode compartment.

680,441. August 13, 1901; B. E. F. Rhodin, Sault Ste. Marie, Can.

Anode for cell of patent No. 680,440, consisting of a supporting block of carbon having vertical threaded openings through which pass threaded carbon rods, construction permitting adjustment and renewal of rods.

692,531. February 4, 1902; E. A. Le Sueur, Rumford Falls, Me.

Outer iron cathode vessel, filled with water, receives electrolyzing chamber, a wooden cement-lined frame closed below by horizontal amalgamated wire gauze, the mercury acting as a bipolar electrode. A layer of gravel may rest on wire gauze. Level of brine in electrolyzing chamber somewhat lower than that of water outside, to give equal pressure on both sides of amalgamated gauze. A plurality of anodes, each consisting of platinum filaments radiating from a central stem, sealed in a glass tube. May connect cathode terminal directly to wire gauze.

693,678. February 18, 1902; G. M. Wilson, Sault Ste. Marie, Can.

Side passages carry amalgam from electrolyzing chamber into oxidizing chamber. Horizontal paddle wheel sweeps depleted mercury back over a dam and beneath vertical partition into electrolyzing chamber. Provides feed and overflow pipes in each chamber.

695,302. March 11, 1902; J. D. Gilmour, Glasgow, Scotland.

Electrolyzing chamber with carbon anodes and mercury cathode, placed within oxidizing chamber. Two series of short pipes extend from the lower portion of the outer chamber into and slightly above the bottom of the inner chamber. The outer vessel contains a layer of mercury and is filled with water. A pump continuously varies the pressure of the water and forces mercury up through one set of pipes into the electrolyzing chamber, while the amalgam flows out through the other set into the electrolyzing chamber. The caustic liquor overflows from the outer vessel at each pulsation of the pump.

699,401. May 6, 1902; C. J. Reed, Philadelphia, Pa.

In order to fully oxidize the sodium contained in a bipolar mercury electrode without oxidizing the mercury, and at the same time utilize the resulting current, employs a greater number of electrolyzing chambers than oxidizing chambers, and thereby causes the amalgam in each oxidizing chamber to contain sufficient sodium to transmit the entire current. The cathode of each electrolyzing cell consists of a series of amalgamated copper discs rotating on a horizontal axis and provided with curved grooves to distribute mercury, into which the lower edge of each disc dips, evenly over their faces. A carbon-plate anode depends between each pair of discs. In order to convey the depleted mercury from an oxidizing chamber to the next electrolyzing chamber without permitting the electric current to flow, uses a non-conducting transfer wheel with a series of pockets, which dip up and deliver the mercury in separate globules.

699,415. May 6, 1902; C. J. Reed, Philadelphia, Pa.

The electrolytic cell has in its bottom a plurality of parallel pockets filled with mercury. An amalgamated sheet-metal cathode is arranged over each pocket, being either a plate with means for vertically reciprocating it into and out of the pocket, or a disc carried by a horizontal revolvable shaft, with its lower edge depending into the mercury. The disc has curved grooves, which assist in taking up the mercury and distributing it over the surface of the disc. A carbon anode, which may be surrounded by a porous cup, depends between each pair of cathodes. The amalgam in the pockets is removed and replaced by mercury, as desired. The amalgam may be carried from the electrolytic cell into an oxidizing cell of similar construction, and the depleted mercury may then be delivered to a second set of electrolytic cells by a rotating transfer wheel having a series of pockets, which dip up and deliver the mercury in separate globules.

## SAULT STE. MARIE.

The opening of the hydro-electric plant of the Michigan Lake Superior Co., at Sault Ste. Marie, which is exceeded in size only by that at Niagara Falls, marks a new epoch in the development of this young industrial center. Under the energetic management of the Clergue Syndicate, the development of the Canadian "Soo" has been rapid in recent years. Now, after the opening of the Michigan power house, the development of the American side promises to be not less impressive. Nor should there be any doubt that the development of the "Soo" in the future will be closely allied with the advance of electrochemical industries.

Perhaps the most important condition which determined the general engineering features of the new power plant was the low available head of only 20 feet. It necessitated the installation of a great many generating units of comparatively small size. The total capacity of the power house is 32,000 kilowatts, in 80 units of 400 kilowatts each. This large number of small units accounts for the enormous size of the plant.

We publish in this issue an interesting article by Dr. J. W. Richards, on the present industrial conditions of the "Soo" and on the outlook for the future, especially with respect to electrochemical industries. The main reason why one may safely prophesy that the development of the "Soo" will be closely allied with electrochemical enterprise is the fact that the distance of Sault Ste. Marie from any large city is too great to justify transmission of power. The power generated there is to be consumed at the spot. The location is very favorable for cheap transportation of the goods, either by water or on railways. The conditions are therefore fulfilled which should enable the "Soo" to become an important industrial center, like Niagara Falls. In fact, the marvelous development of the "Soo" in the last few years leaves no doubt concerning the future. Electrochemical industries have already participated in this development. There is the alkali plant, using the Rhodin process, which, however, is not in operation at present. For the manufacture of calcium carbide, a large amount of the power of the new power house has already been contracted for. And last, but not least, there are very promising prospects for developments in the electrometallurgical line, especially for the treatment of Lake Superior copper and Sudbury nickel.

It is perhaps superfluous to remark that electrochemical plants, with their uniform continuous load and their very high load factor, are the ideal customers for a great power plant, and that therefore the managers of power plants are fully justified in making special inducements to electrochemical enterprise. We wish great success to the energetic managers of the enterprise at Sault Ste. Marie, and we trust that in future we may often have to record advances of electrochemistry and electrometallurgy at the "Soo."

## LOW TEMPERATURE RESEARCHES.

We need offer no apology for devoting much space this month to the publication, nearly in full, of Prof. James Dewar's presidential address to the British Association on this subject, which, although not directly electrochemical, is of the highest interest, as it refers to a field on which very little is yet known and which may become of great importance in the future. Professor Dewar's extended researches in this field render his address an authoritative statement of our present knowledge in this line.

Electrochemical processes, as far as they are not performed at ordinary temperatures, have up to the present been essentially high temperature processes. The electrical furnace is the ideal means of producing high temperatures, which are, indeed, limited only by the difficulty of finding sufficiently refractory materials for the furnace walls. Electric furnace researches have given us a new chemistry—that of high temperatures—and these researches have already brought many fruitful industrial results. There is great difficulty in these researches, in so far as it seems impossible at present to predict what one will get in such a process. In fact, a very prominent investigator and pioneer in this line once stated in a private conversation that it is impossible to work according to a clearly predetermined plan; the only way is to put materials into the furnace, turn on the current and wait to see what one will get. This may seem a rough and unscientific way, but it nevertheless states correctly the limits of our present knowledge.

There is, indeed, a remarkable difference between the chemistry at high and at low temperatures. Prof. J. H. van't Hoff has emphasized this difference in one of his lectures on physical chemistry, held at the celebration of the tenth anniversary of the University of Chicago last year, while discussing Berthelot's "principe du travail maximum." This principle is very simple. It states that the amount of heat which a chemical action evolves indicates at the same time in which direction the reaction will occur. If there is a possibility of the evolution of heat by means of a chemical reaction, this reaction, and not the reverse, will take place. Indeed, this principle is correct in a great many instances, and is a very useful means to predict, under normal conditions, what will happen. But there are cases where the actual facts clearly contradict this law. Professor van't Hoff points out that when one considers this matter from the point of view of the second principle of thermodynamics, then Berthelot's principle appears to be correct at temperatures near the absolute zero point. That Berthelot's principle is found to agree with so many observations in ordinary chemistry is simply a result of the fact that at the ordinary temperature of chemical experiments we are relatively near the absolute zero of temperature. At 1,000° Celsius the processes occur in a quite different manner, and often in a way which is opposite to Berthelot's principle. The lower the temperature the better we are able to predict things by means of Berthelot's principle. Whether the low temperature researches will have important industrial results can only be borne out by the development of the future, but it must be said that it is quite likely that this will be the case

## FARADAY'S LAW AND THE THEORY OF ELECTRONS.

In this issue we publish an article on this subject which we believe may be of interest to the practical electrochemical engineer. The modern hypothesis of electrons is usually regarded to be of theoretical value only, and practical men are somewhat inclined to scorn it. In the article to which we refer an attempt is made to show that this hypothesis ought to be useful to the practical man, as it offers a very simple and safe means of applying Faraday's law, which should certainly not be despised, as it is surprising to see how often mistakes are made in numerical applications of this fundamental law of electrolytic action.

Most electrochemical text-books state Faraday's law either in too vague or too narrow a sense. We say "too vague," as very often this law is given more qualitatively than quantitively. But what the engineer needs is an exact, concise method by which he can calculate numerically in any case the theoretical output in pounds or kilograms per ampère hour. The law is also given in too narrow a sense, by stating merely the relation between the ampère hours and the weight of ions "liberated at the electrodes." One, then, cannot apply it to cases in which no ions are liberated, but where there is a simple change of valence, as at the carbon electrode in the Bunsen cell or in the chromium cell. It is indeed difficult to give briefly a complete and concise statement of Faraday's law, and it is much easier to form a mechanical model or image suitable for all cases and based upon the hypothesis of ions and electrons. Of course, if such a hypothesis is useful for such purposes, this should not be taken as a proof of the complete correctness of the hypothesis, and one should bear in mind that the use of such mechanical models is comparable to using crutches in walking. But it is certainly better to reach a goal safely by means of crutches than not to reach it at all.

It is interesting to note how closely Professor Johnson's notation of "bonds," which was based purely on chemical considerations, applies to electrochemical problems if only positive and negative bonds are considered as positive and negative electrons. This is an example showing that in natural science there are many ways by which one may approach a certain goal, but the final result must always be the same if it is to represent the truth. Yet the same truth may be expressed in different ways or by different images, according to the point of view from which one looks at it.

## STORAGE BATTERY INVENTION.

In this issue we publish an article by Prof. A. L. Marsh, on the thallium storage cell, which is quite interesting in several respects from a scientific point of view, although, as the author states, it is unsuitable for the purposes of the practice. The principal reason why this cell must fail in practice is that the electrodes are not insoluble in all states of charge and discharge. From the experience of a great number of inventors, who for a long series of years have made extended experiments and trials with new storage batteries, it seems safe to conclude that the solubility of an electrode in any state of charge or discharge is fatal to the commercial success of the

battery. It is worth while to discuss this point somewhat in detail.

There are two reasons which may cause the failure of a battery due to solubility of an electrode. The first refers only to batteries with electrodes of two metals. For instance, should in a zinc-copper cell with an alkaline electrolyte copper go into solution, the copper ions will go to the zinc electrode during charge, and will be deposited on the zinc; this copper deposited on the zinc will form, together with the zinc, a short-circuited couple, and zinc will be dissolved, the total chemical energy lost being changed into Joulean heat. In its result this is equivalent with local action. In the same battery zinc goes into solution, but it is not deposited on the copper; hence there is here not the same disadvantage inherent in the solubility of the zinc as in the solubility of the copper. From this the rule results which has been recognized as correct for years—that in a storage battery with electrodes of two different metals the electrode, which is the cathode during discharge (or the anode during charge), should be insoluble in any state of charge or discharge. Of course, this rule has no effect on the thallium cell, because thallium is the only metal used in this cell.

The second reason why no soluble electrodes should be used is of universal importance, and is pointed out clearly by Professor Marsh when he speaks of the difficulties of obtaining compact, evenly-distributed and adherent deposits. The experience of electroplaters proves that to get good adherent deposits of any metal special conditions must be carefully observed. It is evident that this is strictly impossible in storage-battery practice. Hence during charge there will always occur deposits in spongy or not adherent form, and this will result in short circuits. This has been proven conclusively by the trials which have been made with the zinc-lead peroxide accumulator, which has otherwise distinct advantages over the ordinary lead cell.

The rule that a storage cell should not contain any soluble electrode is fulfilled in the lead cell, and is claimed to be fulfilled in the Edison iron-nickel accumulator, which may be considered at present as the most promising rival of the lead cell. Edison's iron-nickel cell has just this advantage of the unsolubility of the electrodes over the old Edison-Lalande cell. While the thallium cell—or the general type of which it is a special case—has certainly distinct interesting features, which are clearly brought out by Professor Marsh, there cannot be any doubt that neither this cell nor any other cell of the same type is applicable for commercial work.

## CAUSTIC SODA BY THE DIAPHRAGM PROCESS.

In the first two issues of this journal we published, in the Digest of United States Patents, prepared by Messrs. E. A. Byrnes and C. P. Townsend, a complete review of the patents referring to the electrolysis of sodium chloride with mercury cathodes. We commented editorially in our last issue upon an important point in connection with this class of processes. In our present issue we publish the first part of the review of the patents referring to diaphragm processes.

It is a chemical commonplace that the rate of chemical change is proportional to the active mass of the reacting substances, and that the only chemical changes which are truly complete are those in which one at least of the final products assumes a physical condition which withdraws it from the sphere of reaction. This mass law has its direct applications to electrolytic work, but, without following them too closely, it may be remarked that in general the electrolytic methods which work at high efficiency are those in which one at least of the products passes into an insoluble state, or is otherwise withdrawn from the field of electrolytic action. If the physical character of the resultant product, primary or secondary, is such as to insure its isolation, the efficiency will be high.

It so happens, however, that many of the most important industrial electrolytic products are soluble in their electrolytes, either directly or by reaction therewith, and it is around such that the most formidable difficulties cluster. Since they are not isolated by virtue of their physical state, it is essential that means be provided for shielding them from the influence of the current and of the electrolyte, and from this necessity has arisen the type of diaphragm cells.

Caustic soda occupies the peak of the trouble line. If the metal sodium be absorbed by a mercury cathode, and by it carried from the region of reaction, the field is left clear and the efficiency is high. If, however, it be permitted to oxydize at the cathode, the efficiency will depend directly upon the effectiveness of the means employed for the restriction of the caustic solution to this point. For this reason, and because, to an investigator, failure has much the same value as success, provided only the causes be recognized, there is no more suggestive field for study than the efforts, past and present, to compass the direct conversion of brine into caustic.

## ELECTROCHEMICAL TERMINOLOGY.

The Standardization Committee of the American Institute of Electrical Engineers has done excellent work in standardizing methods of testing and paving the way towards the use of a uniform terminology in electrical engineering. We hope the American Electrochemical Society will undertake the same task for industrial and scientific electrochemistry, for it cannot be denied that at present a great confusion prevails in electrochemical terminology. We may only call attention to the different sense in which the terms positive and negative plate of an accumulator are used. In scientific electrochemistry a great deal of very valuable work has been done in Germany, but it must be said that the terminology introduced by the Germans is often misleading, and often, when the German terms are correct, the translation is wrong. For instance, Kohlrausch's "Beweglichkeit" of an ion is usually translated as ionic speed or velocity, which is simply wrong, because the dimensions are not those of a velocity. Finally, the notification in books on electrochemistry should be simplified; it should agree with that generally used by electrical engineers.

Electrochemical engineers and scientists should remember that they are workers in the same field, and the American Electrochemical Society should use their authority to bring about uniformity of terms and notation.

## THE OPENING OF THE WATER WORKS POWER PLANT AT SAULT STE. MARIE, MICHIGAN.

At noon, October 25th, occurred the formal opening of the water-power plant of the Michigan Lake Superior Power Co. at Sault Ste Marie, Mich. The event is an important one, not only to the citizens of that locality, but to the electrochemical industry in general, because it marks the beginning of operation of the second largest water-power electric plant in this country. All of the important features of the hydraulic installation at this place are described in the article by Dr. J. W. Richards on another page of this issue.

Mr. H. von Schon has been chief engineer of the undertaking. Mr. W. Owen Thomas is electrical engineer in charge of the electrical work, and designed many of the interesting electrical features.

At the present time the market for the company's electrical output is practically undeveloped at the Soo, and there is abundant power for industries desiring cheap electrical power. The investment in the completed plant will be, it is announced, about $4,000,000, or $135 per kilowatt. This is not high as investments in water plants run, and the company ought to be able to make a very low rate.

At the formal opening, on October 25th, shortly after noon, Chief Engineer von Schon spoke a few introductory words. Mr. F. H. Clergue, the head of the whole enterprise, answered briefly, and Miss Helen Clergue then stepped forward and, by closing the switch, set the machinery in motion.

A banquet on the evening of October 27th closed the festivities.

---

## ELECTROCHEMICAL UNITS.

In our last issue (page 60) we published a longer abstract of Mr. Alfred H. Cowles' interesting American Electrochemical Society paper, in which he proposes a new system of electrochemical units, based upon the following very simple relation found by him: 100 ampères liberate one cubic meter of hydrogen in one day. We are indebted to Mr. Cowles for the following additional information:

Based upon this relation, he proposes that this quantity of electricity be called a kilocrith col, as the weight of a cubic meter of hydrogen is a kilocrith, or 1,000 criths. The calculation from which the foregoing agreement is found can be made from the following data: In the "Smithsonian Contributions to Knowledge" for 1896 is printed Dr. Edward W. Morley's classic paper on the atomic weights of oxygen and hydrogen. In the same he gives the weight of a crith, or one cubic decimeter of hydrogen, as .089873 = .000027 grams at 0° C., 45° Lat, and at the mean atmospheric pressure at sea level. If the atomic weight of hydrogen be taken as one, we must then attribute an atomic weight of 107.11 to silver, and, taking Lord Rayleigh's determination of the electrochemical equivalent of silver, .001118 grams per coulomb, the electrochemical equivalent of hydrogen becomes .00001043786 grams. Under these premises, the kilocrith col, or 100 international ampères, for one siderial day liberate 1.00071 cubic meters of hydrogen under normal conditions. Of course, this can be reduced to a crith col by dividing in each case by 1,000, in which case we have the electric quantity that will free a crith or liter of hydrogen.

We may use this opportunity to correct a typographical error which occurred in our abstract in the last issue, where, in stating the above relation, one cc. was said, instead of one cubicmeter. The two remarkable relations found by Mr. Cowles are exactly stated, as follows: First, 500 ampères in one solar day decompose practically (within ½ per cent.) one pound (avoirdupois) molecule of any univalent compound; and, second, 100 ampères in one siderial day liberate one (exactly, 1.00071, from the best available figures) cubic meter of hydrogen under normal conditions.

## DEVELOPMENTS IN ELECTROMETALLURGY OF IRON AND STEEL.

An interesting paper on this subject, which appears to become of commercial importance, was read at the Niagara meeting of the American Electrochemical Society, by Marcus Ruthenberg. It is well known that many iron ores occur throughout the world, which are too low in tenure to permit smelting. If the iron in these ores occurs as magnetite $Fe_3O_4$, it permits of a concentration by means of magnetic separators. Magnetites occur but seldom of such purity that they are entirely free from sulphur and phosphorus, and it depends very largely upon what portion of the ore these two metals are associated with, as to the fineness to which the ore must be ground, and its particular treatment in the magnetic machines. It is found that when ores are ground finely and an attempt is made to magnetically concentrate them dry, there is a measure of adhesion between the particles of magnetic and non-magnetic portions that will not permit of cleanly work; this is obviated by handling the ground ore in water, in which case the water seems to lubricate the particles so that the magnetic portions come away cleanly. A clean, fine, blue-black powder is thus obtained which may go anywhere from 65 to 72 per cent. of magnetic iron, pure peroxide being 72.40. It then becomes a question as to how this iron ore may be handled in a furnace. The author discusses critically several methods which can be used and have been suggested for this purpose. He then describes an entirely new method which he has had in use for upwards of a year.

This method consists in taking the concentrates cleaned up to the highest point of possible purity, and putting them through an electric furnace, the melting zone of which is a magnetic field. The ore being magnetic, and the polar projections of this magnetic field being at the same time the electrodes of the smelting circuit, the magnetic bridge thus formed by the ore forms a high resistance in the smelting circuit. The heat of the smelting circuit is engendered within this bridge of ore itself. The electrodes are water-cooled. The moment that the ore melts it loses its magnetism, and gathering weight from new molten material being added to it, it falls out of the magnetic field, its place being taken by fresh portions of ore from above. The result of this operation is agglomerated, coherent masses, ranging in size from a bean to a walnut, that are hard, strong, tough and porous, differing in analysis in no way from the ore prior to its agglomeration except for the absence of moisture and the last traces of sulphur. The product is in an ideal condition for use in the blast furnace.

If reducing material, such as powdered coke dust or charcoal dust be added to the charge prior to its introduction to the electric furnace, a partial reduction takes place and the fritted mass of carbonaceous dust and iron ore, partially reduced, is dropped into a soaking pit. If allowed to remain in this soaking pit a proper length of time, cementation takes place through the action of the heat left in the ore, by the electric furnace, and the action of the carbon fritted into the mass, which results in producing reduced metal, which may be properly termed steel. This material from the soaking pits is ideal for melting in the open-hearth furnace. It thus becomes possible to produce first-class steel direct from the ore, through the intermediation of the electric furnace and the soaking pit, producing spongy iron or steel ready for immediate melting in the open hearth, without the intervention of the blast furnace in any part.

The author believes that this process could be used to great advantage for many low-grade ores. He especially refers to ferruginous beach sands which occur in many parts of the world, notably on the St. Lawrence River and on the Pacific Coast.

For further details, the reader must be referred to the full paper, published in the "Transactions" of the Society, which will come out at the end of this month.

## ELECTROCHEMISTRY AT SAULT SAINTE MARIE.

By JOSEPH W. RICHARDS,
*President of the American Electrochemical Society.*

A DESCRIPTION kept conscientiously within the above title would be very brief. It would cover a description of the Rhodin process of manufacturing caustic alkali and bleaching powder and would then stop, for that is the only electrochemical process at present installed at "the Soo." With the indulgence of the reader, we will therefore digress from the straight and narrow way and use the above title as a text under which we will speak of the general situation of Sault Ste. Marie, its facilities for manufacturing and its potentialities in the electrochemical line.

First, as to the power there available, the St. Mary River is the outlet of Lake Superior, which, with its 30,000 square miles of surface, is the largest body of fresh water on the earth. The river runs over rapids about half a mile long, with a total fall of 20 feet. This head is made available by constructing canals around the rapids, and thus conducting the water to power houses below them. The discharge varies with the season and the winds, but is, at its lowest, 3,000,000 cubic feet per minute, representing a total of 135,000 horse-power. This is however to be diminished by the loss in conversion into mechanical and electric power, and by the fact that in order to give flow through the intake canals, some of the head must be sacrificed, and only 18 feet of head can be counted on at the power houses. Allowing for these, the minimum available electric power of Sault Ste. Marie is about 110,000 horse-power. More than this might be generated at times, but it will hardly pay to install a power plant in excess of this, part of which would either be idle or run at only a fraction of its capacity for part of the year.

The present utilization of the power includes a 20,000 horse-power house on the Canadian side, owned by the Lake Superior Power Co., and a 40,000 horse-power plant on the American side, owned by the Michigan Lake Superior Power Co., so that 60,000 of the possible 110,000 horse-power is already taken care of.

The American plant has just been completed. The water-power canal is over two miles long, and traverses the city of Sault Ste. Marie, Mich. It is 200 feet wide, 25 to 27 feet deep, cut partly through red sandstone rock and partly through red clay, and will be capable of delivering some 20,000 cubic feet of water per second. It was an expensive canal to construct, the bottom being in places planked over to avoid scouring, and eight steel bridges being necessary where it crossed streets. The power house is on the river edge, and is 1,340 feet long, 87 feet wide and 107 feet high, built in a most substantial manner of sandstone, on pile foundations. It is divided into 80 divisions, to each of which is a set of four 125 horse-power turbine wheels, actuating a 500 horse-power dynamo on the floor above. Current for near-by industries will be generated at low voltage and of the amperage needed; for distant use it will be transmitted at high voltage. The canal cost $3,000,000, the power house, with docks and equipment, $1,000,000, making a total cost of $4,000,000. If we estimate the interest which this money should earn at 10 per cent., the cost of maintenance and labor at 2½ per cent. and depreciation at 2½ per cent., the price which this power should command, as electrical horse-power, is about $15 per horse-power per year. The statements are made officially that industries which contract for this power at $20 per horse-power per year will be furnished sites free, and will be exempted from borough taxation for five years, but unofficial statements are current to the effect that some of this power may be had for prices nearer to $10 per horse power per year than $20.

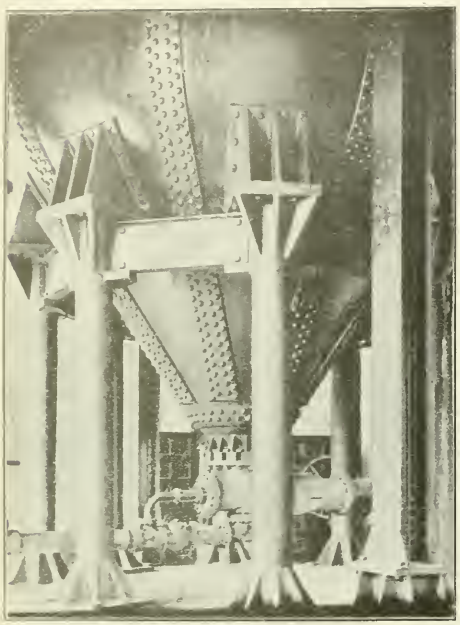
GENERAL VIEW OF THE CANADIAN SIDE

Showing from the left to the right the Canadian Electrolytic Alkali Co. the power house, wood pulp mill, sulphite pulp mill, iron foundry and office building.

The Canadian plant is situated alongside of the Canadian lock and, with a 100-foot wide canal, is generating at present 20,000 horse-power. This power is almost all in use, the larger part being taken by the Sault Ste. Marie Pulp and Paper Co., who have the largest ground wood pulp mill in the world, having a capacity of 150 tons of dry pulp and 75 tons of bleached sulphite pulp per day. An interesting combination is the installation of a roasting plant to roast nickel ores from the company's nickel mines at Sudbury. This is placed alongside the wood pulp mill, and the sulphur dioxide gas generated by roasting the ore is passed directly to the pulp mill and there used for bleaching and gelatinizing the pulp in connection with

the lime bisulphite. An iron foundry and a large machine shop use also considerable power. The power plant and buildings are fairly and substantially built, and there is plenty of land in the vicinity for new industries.

About a mile further up the river is a new steel plant, con-



DIGESTER, SULPHITE PULP MILL.
65 ft. high, 17 ft. diameter.

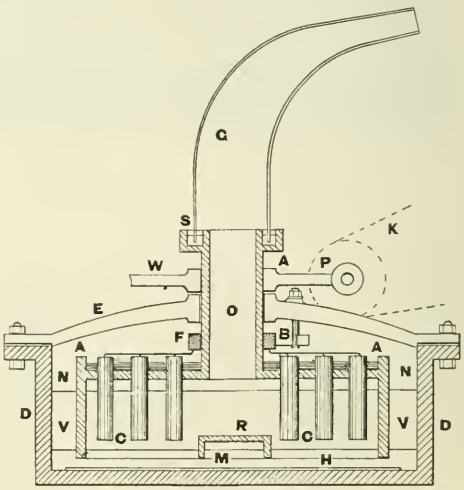
sisting of a large plant of charcoal by-product ovens for obtaining charcoal from hardwood and saving the acetic acid and wood spirit, two blast furnaces—one for making charcoal iron, the other to use coke—and a Bessemer steel mill, with a capacity of 600 tons per day. At these mills the first steel rails rolled in Canada were made, and, since the Canadian Government pays a bounty of $3 per ton on all pig iron made from ore mined in Canada, and an additional bounty of $5 per ton on all steel made in Canada, there should be no doubt as to the profitable operation of this modern plant.

The Rhodin process for making caustic alkali is the only electrochemical process now located at Sault Ste. Marie, and we will describe it at length. Before doing so, however, we will note the statements which are made that 10,000 horse-power on the American side is already contracted for, for the manufacture of calcium carbide, by the Union Carbide Co., and 5,000 horse-power for extensions of the Rhodin process; while it is further contemplated to establish electrolytic plants for refining Lake Superior copper and Sudbury nickel. It is possible that some of these propositions will materialize. Calcium carbide is in very extensive use in Western Canada, as was observed by the writer on a recent trip from Victoria, B. C. The consumption of this chemical is bound to increase largely, as the acetylene light is so well suited to the conditions prevailing in that vast territory. Lake Superior copper can be refined in transit towards the Eastern markets very advantageously at this point, and the same applies to the Sudbury nickel. It is true that navigation is closed for five months of the year, but the railways centering there have given through freight rates to Chicago and other points, which are so low as to practically annul this disadvantage and make the railway transportation as cheap as the water rates all the year around. This statement was made to the writer by Mr. F. J. Clerque, general manager of the Clerque Syndicate, and is therefore official.

The Canadian Electrochemical Co., Ltd., rent power from the Lake Superior Power Co., on the Ontario side, and are installed in buildings owned by that company, close to the Canadian lock. They use the Rhodin process of electrolyzing sodium chloride solution and obtaining caustic soda and bleaching powder. When visited by the writer, September 12th last, they were not in operation, because the war between the chemical and electrochemical alkali companies in Europe had so demoralized the market for the products (bleaching powder being sold by them in Canada as low as $20 per ton) that the plant could not be operated profitably at the low prices.

The installation to be described was considered by the company as a more or less experimental one, which would develop into a large plant on the American side. But while the power for the latter has been contracted for, the company have been unable to take any steps towards erecting that plant, because of financial difficulties, too little of the capital stock of the company having been realized as available cash for erecting the plant. It is hoped that a financial reorganization of the company will enable the American plant to be commenced in the near future.

The Canadian plant consists of three 350 horse-power turbines, each actuating a 200-kilowatt dynamo. Each dynamo runs a row of 40 decomposing cells, connected in series. The current in one circuit is 900 ampères, and the total potential at the dynamo is 220 volts, which, allowing the extra 20 volts for the resistance of the conductors and connections in the circuit, leaves an average drop of 5 volts per cell. The theory of the action of the cell is the decomposition of concentrated brine between graphite anodes and a layer of mercury in a large iron pan as cathode, the anodes being contained in a bell-shaped vessel, which collects and carries away the evolved chlorine, while the mercury charged with sodium escapes under the lip of the bell and passes into the space outside, where, coming



RHODIN CELL.

into contact with water, it discharges its sodium and produces caustic alkali solution. Mechanical arrangements produce a rotation of the bell, the continuous inflow and outflow of brine therefrom and a continuous or intermittent supply of water to the pan outside the bell.

The annexed diagram of the cross section of the cell shows the mechanical details. D is the cast-iron pan, 5 feet in diameter by 1 foot deep, containing a layer of mercury, H, which can scarcely be less than 1 inch in depth, which would imply at least 1,000 pounds weight of mercury in each cell, costing, at current prices, $500. This item will then constitute one of the largest items of cost of the plant. Suspended inside this pan is an inverted earthenware bell, A, 3 feet in diameter, through the top of which pass the graphite anodes, C, which reach down to within 1 inch of the mercury. These carbons are fastened into the holes by pouring cement around them, and are in electrical connection with the copper ring, F, to which the current is conducted by a brush, B.

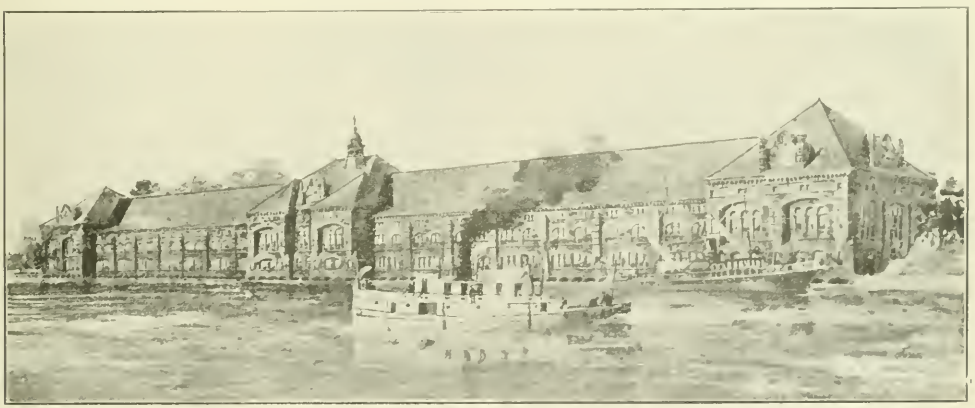
The inside of the bell, sealed off from the outside by its edge dipping beneath the mercury, is partly filled with concentrated brine solution. This is renewed continuously by inlet and overflow outlet pipes passing through the botom of the pan. The fresh brine is fed directly into the field of decomposition, between the carbons and the mercury. The bell is supported by a framework across the top of the iron cell, and has an upward prolongation or tube through which the chlorine escapes. To make connection with the stationary chlorine pipe, the latter dips into a circular water-seal on top of the prolongation, as shown in the cut at S. The bell is rotated by a worm and gear, thus bringing the carbon anodes continually over fresh surfaces of mercury. The brine is thus given a rotary movement also, which further imparts itself to the mercury, and the latter, by means of radial grooves in the bottom of the iron pan, is by that means continually forced towards the outer edge of the pan.

Outside of the bell there is water resting upon the mercury, which acts upon the amalgam and produces caustic soda, with liberation of hydrogen. This solution is allowed to stay until it becomes quite strong, and is then run off by a siphon pipe and replaced by fresh water. It was stated by the inventors that the iron pan was heated externally to nearly the boiling point of the solutions, resulting in preventing the brine keeping so much chlorine in solution and increasing the efficiency of discharge of the amalgam, as also reducing the electrical resistance of the cell. This information, however, was altogether at fault, for above 75 degrees chlorate is formed in large quantity, destroying the anodes and causing great danger of explosions from the admixture of oxygen with the chlorine. The real facts are that the passing of 900 ampères through such a cell, 3 feet in diameter, heats the liquid by its own resistance much more than is desirable, and the problem is rather how to keep the cell cool than to heat it.

The theoretical difference of potential required to decompose a saturated brine solution and to form sodium and set free chlorine is [illegible] = 4.22 volts. The absorption of the sodium to form amalgam, however, gives out considerable energy, which is returned as e. m. f. to the circuit; this amounts to [illegible] = 0.89 volt. The voltage absorbed in decomposition is therefore 3.33 volts. The actual voltage used to force 900 ampères through is 5 volts, which leaves, therefore, 1.67 volts absorbed in overcoming ohmic resistance, and represents electrical energy converted into heat. This is equivalent to a generation of about 45 pound calories of heat per minute in the apparatus, sufficient to heat it and its contents about 20° F. in an hour if no heat were radiated. We see that it is therefore quite likely that the apparatus will rush some 20° F. above the outside room temperature simply from the heating effect of the current.

In such an apparatus it is likely that there will be some loss by re-combination of sodium in the anode compartment. There is no positive removal of the amalgam from the bell, neither is there a positive method of discharging it outside. These two operations take place at their own pace, so to speak, and therefore will lag behind the charging action with such a heavy current. Mr. Rhodin has stated the loss by re-solution at the brine surface as 3 per cent. It might have been anticipated as still larger. The discharge is voltaic in its nature, for the iron pan and amalgam form a short-circuited voltaic couple, which, when moistened by the water, causes the discharge of the sodium and the evolution of hydrogen from the iron. This action differs from the Kellner method of discharging amalgam, in that the latter uses a distinct cathode plate in the caustic solution, separated from and not in physical contact with the amalgam, and thus constituting a galvanic cell, of which the amalgam is one pole and the wire from the cathode plate the other pole, and from which a useful galvanic current can be extracted and utilized, as Kellner utilizes it in his German patent, in assisting the main current used for decomposition in the cell or for any other exterior purpose.

With the voltaic couple action of Rhodin there is no usefully available e. m. f. generated, and the whole energy of decomposition of the amalgam, representing one-fifth of the whole current energy used in the apparatus, heats up the caustic soda solution, and thus increases the temperature of the apparatus. Using Kellner's or Castner's arrangements, whereby the galvanic e. m. f. of this cell is restored to the circuit, only as much of this energy is converted into heat in the caustic solution as is necessary to overcome the ohmic resistance between the cathode and anode in this solution,



MICHIGAN POWER BUILDING.

which, with properly-shaped cathodes, should be *less* than the galvanic e. m. f. of the cell.

The whole installation consists of 120 of these cells, but only 80 have been in operation at once. The bleaching-powder plant consists of 10 chambers, each 55 feet 6 inches long, 17 feet wide and 6 feet 6 inches high, made of No. 6 sheet lead, and with a 2-inch tile floor. The lime plant can furnish 14 tons of slaked lime daily. With 80 cells in operation, the output was 4.4 tons of bleaching powder and 2 tons of caustic daily. This represents about 80 per cent. of the theoretical output for the current used.

The salt used contained 99.5 per cent. of sodium chloride, the rest being mostly calcium and sodium sulphates. These and the free chlorine cause about 1-20 of 1 per cent. of mercury to go into the brine, but, as the solution is used over and over, this causes no loss, except when the brine is changed because of becoming impure, and then, every three or four weeks, about 20 pounds ($14 worth) is lost. In the alkali solution one pound of mercury (worth 70 cents) is dissolved for every 27,500 pounds of caustic produced. This loss is therefore negligible from a commercial standpoint.

If the whole 120 cells were operated, the 4 tons of caustic soda and 9 tons of bleaching powder which it would produce daily would supply all of the latter consumed in Canada and a considerable proportion of the former, but at present market prices in Canada, without a protective tariff, the plant cannot be profitably operated.

## THE THALLIUM STORAGE CELL.

By A. L. Marsh.

THE oxides of thallium are possessed of properties which place them in a new class of electrode materials. The lower oxide, thallous oxide ($Tl_2O$), is soluble in water, while the higher oxide, thallic oxide ($Tl_2O_3$), is insoluble in water and in potassium hydroxide solutions. No other metal forms oxides which bear to each other the above relations. Silver, perhaps, comes the nearest, but differs in that its lower oxide is only very slightly soluble in water.

Thallic oxide in a hydrated state is an almost black compound, resembling lead peroxide. It is a conductor of electricity, and is deposited on the anode from alkaline solutions, just as lead peroxide is deposited from a nitric acid solution. Thallous oxide, or rather the hydroxide (TlOH), is very soluble in water, and is a more stable compound than the thallic oxide. Metallic thallium can be readily deposited from its water solutions by the electric current. In ease of deposition, it stands near the metals lead and cadmium. Here we have the essential features of the thallium cell: For the negative, a metal which may be easily deposited from its water solutions; an electrolyte of thallous hydroxide (TlOH) which is the product of oxidation at the negative or reduction at the positive; and for the positive thallic oxide, an easily-reducible compound, a conductor of electricity, and capable of being deposited on the anode from an alkaline solution.

In charging a cell using a thallous oxide electrolyte, both the positive and the negative active materials are formed from the electrolyte, while on discharging the cell the process is reversed; the materials at both electrodes return to their original condition as electrolyte. There are only two oxides of thallium known, and these, together with the metallic condition, constitute the exact number of chemical changes necessary to the storage of electrical energy in the form of chemical energy in the so-called storage battery. Many metals, under a given set of conditions, are capable of a number of changes in excess of the required number, and therefore introduce complications.

Thallium was discovered in 1861 by Crookes, with the aid of the spectroscope. In examining some seleniferous flue dust from a sulphuric acid manufactory in the Hartz Mountains, Germany, a bright green line was discovered in the spectrum, and the new element was given the name thallium, which is derived from the Greek word meaning "green," or "a young shoot." The honor of having isolated the metal and establishing its true character belongs to Lamy.

The element occurs in small quantities, but is widely distributed in Spanish and Belgium pyrites. In some of these ores the quantity of thallium reaches as high as 3.5 per cent. It is also found in certain mineral waters, and in some specimens of mica and lepidolite. Mother liquor from zinc works in the Hartz Mountains contains about .05 per cent. of thallium. A rare Swedish mineral called Crookesite contains as high as 18 per cent. of this metal. Its chief source at present is the flue dust of sulphuric acid works.

The metallurgy of thallium is comparatively simple. The flue dust is extracted with water, and the thallium precipitated as thallous chloride (TlCl) with hydrochloric acid. This is dissolved in sulphuric acid, and from the resulting solution metallic thallium is precipitated by metallic zinc or by electrolysis.

Thallium bears a great resemblance to lead. It has a silver-like luster at a freshly-cut surface, but tarnishes rapidly in the air. It is malleable, but not ductile. Its specific gravity is 11.8; specific heat, .0325; melting point, 294° C.; atomic weight, 204. Nitric and sulphuric acids dissolve the metal readily, but hydrochloric acid has little action upon it. Surfaces of the metal exposed to the air become yellowish. The yellowish film readily dissolves off in water, and the surface regains its metallic appearance.

There are two series of compounds, the thallous, in which thallium is monovalent, and the thallic, in which the metal is trivalent. Thallous oxide ($Tl_2O$) is a black compound, formed by heating the hydroxide (TlOH) to 100° C. in such a manner as to avoid further oxidation. The hydroxide is formed by exposing the metal to the action of air and water or by adding baryta water (barium hydroxide solution) to a solution of the sulphate. $Tl_2SO_4 + Ba(OH)_2 = BaSO_4 + 2TlOH$. Barium sulphate is a white precipitate, and thallous hydroxide remains in solution. From a concentrated solution crystals having the composition $TlOH, 2H_2O$ are deposited.

Thallic oxide ($Tl_2O_3$) may be prepared by burning the metal in oxygen. By adding a solution of sodium hypochlorite to thallous chloride, a brown precipitate is formed, having the formula $Tl(OH)_3$ (thallic hydroxide). By electrolysis of a solution of thallous oxide, black thallic oxide is deposited on the anode, probably in the form of a hydrate. Having now described the occurrence, properties and compounds of thallium, we will describe the thallium cell more in detail.

A cell was constructed as follows: A small glass vessel was partly filled with a dilute solution of thallous oxide, to which about 10 per cent. of potassium hydroxide was added to increase the conductivity. Electrodes of thin sheet iron, about 1 inch square, were covered with the electrolyte, and the cell was closed with a cork stopper. Upon sending a current of about one-quarter ampère through the electrolyte, spongy thallium separated on the cathode and thallic oxide on the anode. The thallic oxide deposited in a hard black coating, which had a tendency to scale off in places as the layer increased in thickness. There was no gasing, even when the current density was considerably increased. When the charging current was stopped and the cell short-circuited through a galvanometer, comparatively large currents could be obtained. No instrument was at hand for accurate measurement of the electromotive forces. However, indications were that it was little more than .5 volt.

The theoretical storage capacity of thallium and its oxides is very low, the value for thallic oxide being about 53.2 ampère hours per pound, and that for metallic thallium, used as the negative, about 59.5 ampère hours per pound. The corresponding figures for lead peroxide and metallic lead being respectively 101.6 and 117.3 ampère hours per pound, those for silver peroxide (AgO), positive and metallic iron negative, are respectively 195.7 and 433.3 ampère hours. While the theoreti-

cal capacity of thallium and its compounds is extremely low, yet it is much higher than has been obtained in practice by the use of any metal.

Comparing the thallium cell with the lead type, we find the following points of difference:

1. In the lead cell the active materials, both positive and negative, are insoluble* throughout the cycle of changes. In the thallium cell the active materials at both poles are insoluble during the charged state, and both soluble in the electrolyte when discharged.

2. The active material of the lead cell being insoluble when discharged, the charged or peroxidized particles are soon surrounded by the products of discharge, and a large proportion of the peroxide mass is prevented from taking part in the discharge, so a large proportion of the plate is inactive or is dead weight. In the thallium cell, as fast as the peroxide is reduced by discharge, the resulting compound goes into solution, and so leaves the remaining material fully exposed to further action.

3. With lead electrodes, the active material is securely fixed in a suitable grid once for all, while with the thallium cell unattacked sheets of metal suspended in the electrolyte receive a deposit at each charge and lose it at every discharge.

4. With the lead cell, the electrodes must undergo a forming process before they are ready for service, while with the thallium cell no such process is necessary.

5. In lead cells gasing occurs more or less throughout charge, and becomes violent towards the end. No gasing occurs in the thallium cell, unless it is at the end of charge, when the action has been carried too far and the electrolyte has been exhausted of thallous oxide.

6. In the lead cell, the active materials not being deposited from the solution, there is not introduced the difficulty of obtaining compact, evenly distributed and adherent deposits, that gives so much trouble in the thallium cell and in all others having soluble products.

7. The lead cell gives a high electromotive force while the thallium cell gives a low one.

8. The voltage must not fall below 1.6 in the lead cell, while in a cell of the thallium type a discharge to 0 voltage ought to do no harm.

9. The theoretical storage capacity of lead is nearly twice as high as that of thallium.

10. The cost of construction is more for the lead cell than for the thallium cell, owing to the preparation and formation of the plates in the former case.

11. The first cost of materials is low in the case of the lead cell, while it is comparatively high for thallium.

The thallium cell makes use of a metal generally considered to be rare. While it most frequently occurs in small quantities, it is quite widespread, being found in many pyritic zinc ores. The price of this metal is about $6 per pound. To show the possibilities of some of the rare metals for storage battery purposes, as far as cost is concerned, I quote from the "Mineral Industry," Vol. VIII, a statement by Mr Victor Lenher:

"It should be remembered that while a use has been found for many of the rare and high-priced elements, there are many more that owe their present market price only to the fact that the demand is limited to specimens for museums or to the small amounts that are needed for research work. For example, in 1895 thorium nitrate sold at $200 a pound, while to-day it can be bought in Germany for $3.33 per pound.

Even a reduction in price to a few dollars per pound might seem at first thought to be a prohibitively high price for a metal to be used in storage batteries, when lead and its oxides can be bought for a few cents a pound. However, this is not necessarily so, if the metal possesses properties specially adapted to storage work. For instance, a battery using a material which insures a long life with hard usage, can be easily utilized again without excessive waste, requires no tedious forming process for its preparation, gives a high capacity, a high electromotive force and a high efficiency, and is capable of retaining a charge for a reasonable length of time, would admit of using a metal whose cost is many times greater than the cost of lead.

High capacity is a very important factor, since the higher the capacity the smaller the amount of material required.

No metal has yet been found that meets all these requirements, or even the greater part of them. Thallium is lacking in many important points, but at the same time possesses some good features. In the first place, a great objection is the fact that it is a difficult matter to obtain good, evenly distributed, coherent and adherent deposits of metal or of peroxide. The peroxide is particularly troublesome, on account of its peeling off the electrode. Otherwise this type of cell would have a decided advantage, in that a fresh surface of active material is always exposed as the discharge proceeds, a large proportion of the material may be utilized and the discharge may be allowed to proceed to 0 voltage. The fact that in the thallium cell the active materials of both electrodes are formed from the electrolyte, and when discharged return to their original condition as electrolyte, ought to be a strong point in favor of long life, for, the electrodes being permanent, the difficulty would be temporary, and could be corrected by properly charging. Each charge is practically the same as putting in new electrodes in the lead cell.

Since the thallium is in solution as the oxide in one part of the cycle makes it easy to utilize the material from worn-out cells. Thallium compounds are easily manipulated chemically.

The fact that the discharge product is soluble in the electrolyte obviates the use of a special forming process. In the matter of capacity, thallium stands very low in the scale; low also in regard to the electromotive force it is capable of producing. Efficiency is a matter not yet determined, but it would probably be low, for the reason that it is difficult to obtain good deposits on the electrodes. There would probably be no difficulty in the retention of charge.

It is obvious that thallium is not a metal from which a practical battery could be developed, not so much on account of its high cost as on account of its non-adaptability to the purpose. Yet the thallium cell should be interesting from a scientific standpoint, from the fact that its higher oxide represents a new type of positive electrode material.

## ANNUAL MEETING AMERICAN ELECTROCHEMICAL SOCIETY.

At the meeting of the Board of Directors of the American Electrochemical Society, held on November 6th, it was decided that the next general meeting will be held in New York City, on Thursday, Friday and Saturday of the week following Easter Sunday, i. e., April 16, 17 and 18, 1903. On Thursday, April 16th, the annual business meeting will be held, at 10.30 A. M., when the results of the election of officers will be announced. The program for the other days has not yet been arranged.

The suggestion to hold in autumn a meeting in Sault Ste Marie, simultaneously with the meeting of the American Institute of Electrical Engineers, was favorably looked upon, but no definite decision has yet been reached.

There appears to be a difficulty in arranging this simultaneous meeting, because the American Institute of Electrical Engineers have usually held their annual summer meeting in the early summer, generally in June. On the other hand, it would be impossible for the American Electrochemical Society to hold again a general meeting in June, so shortly after the annual business meeting, which must be held in March or April, according to the constitution.

* Here, all metals are considered to be insoluble in water or acids. In a strict sense, metals are not soluble in water or acids, but products may result which are soluble in these media.

## PIONEERS OF ELECTROCHEMISTRY—III.

### Edward Goodrich Acheson.

Edward Goodrich Acheson was born in Washington, Pa., March 9, 1856. His education was received at the Bellefonte Academy, Bellefonte, Pa., he finding it necessary to leave in 1872, before completing his course. Immediately after leaving school he joined a civil engineer corps on railroad construction as chainman, and followed this line of work for several years, eventually rising to the position of transit-man.

Acheson had always exhibited an intense interest in scientific subjects, and followed with great interest the newspaper descriptions of Edison's work at Menlo Park, being finally so captivated with electrical studies that he determined to seek a position in that line of scientific work. He was at that time living in the Pennsylvania oil fields at Bradford, in the employ of the Standard Oil Co. He resigned this position, and some little time later arrived in New York City and made application to Mr. Weston, at Newark, N. J., for a position. Failing there, he applied to the Western Electric Co., New York, and in turn several other of the early electrical establishments of that day, finally going to Menlo Park, where he was fortunate in securing employment in Mr. Edison's laboratory in the capacity of draftsman. Mr. Edison seems to have quickly appreciated his worth, and promotion following, he was within two months in charge of original experimental work in the laboratory.

E. G. Acheson

Acting on Mr. Edison's advice, Acheson gave particular attention to the manufacture of the new incandescent lamp, and on July 20, 1881, he was sent to Europe as assistant engineer of the Edison interests abroad. His first duties in the new field were more or less of an official character in the electrical exhibition at Paris, 1881. At the close of the Exposition he was given charge of, and constructed, the installation of the lamp factory in Edison's plant at Ivry-sur-Seine. He later was sent out on a trip through Europe, installing lighting plants at Milan, Pisa, Brussels, Bergamo, Geneo, Antwerp and many other places. Several Edison companies were formed as the result of this tour. Acheson left the Edison interests about the beginning of 1883, and took up private experimental work on electric batteries and thermopiles, the results of which were not satisfactory.

Returning to the United States in January, 1884, Acheson renewed his connection with the Edison interests, but shortly afterwards he again became engaged in private experimental work, which having been carried on for some few months, he accepted the position of superintendent of the Consolidated Lamp Co. of Brooklyn, with whom he remained but a few months, once more returning to his private experimental work on the conversion of heat energy into electrical energy. In 1886, he was appointed electrician of the Standard Underground Cable Co., of Pittsburg, and after filling this position for three years, he resigned and once more returned to private experimental field. In order to have greater facilities with which to carry on his experiments, Acheson organized a local electric-light plant at Monongahela, Pa., which began operations November 20, 1890. With the large power and many facilities at hand, a great variety of experiments were undertaken, one made in March of 1901 resulting in the production of that now well-known material "carborundum." Acheson had made an experiment in Edison's laboratory in the winter of 1880, which was productive of a substance of remarkable hardness, and at that time it occurred to him that it might be of value as an abrasive material. After a lapse of more than ten years, he made the experiment of mixing clay and carbon together, placed it in an iron bowl which was connected with one terminal of his dynamo, and, embedded in the mixture, he placed an arc light carbon, which was connected with the other terminal of the dynamo. A sufficient current to raise the mixture to a high temperature having been passed for some time, Acheson observed a few bright blue and black crystals attached to and surrounding the carbon rod. These crystals he named carborundum, and immediately began its manufacture in a small way. His production for the following six months amounted to about ¼ pound per day, and the material was sold to the lapidaries and machinists for grinding purposes.

The preliminary experiments in the manufacture proving encouraging, a stock company was organized in the fall of the same year, under the title "The Carborundum Co.," and they began operations at Monongahela City. In 1894, the large power development of Niagara Falls approaching completion, Acheson decided to establish a large plant at that place, but his stockholders were unwilling to subscribe to such movement, and Acheson, having disposed of a number of his patents in Enrope, used his own means for the construction of a large modern plant at Niagara Falls. After this plant was in operation, carborundum was produced in large quantities and was correspondingly cheaper in price, but still so much more expensive than emery that the emery-wheel makers refused to buy the material, and it was forced upon the company to enter into the manufacture of carborundum goods. The three years following were devoted to perfecting the manufacture, not only of carborundum, but of the articles made from it, and the material made rapid advancement in its applications to the various arts, in many instances entirely supplanting the emery goods. During this period there was added to the plant a department for the manufacture of carborundum paper and cloth, this proving equally as successful as the other lines of manufacture. It is interesting to note that the first sale of carborundum in 1891 was 200 carats, at 30 cents per carat, or $560 per pound, while in 1901 the output was 3,838,000 pounds, sold at an average price of 10 cents per pound.

Finally, in 1897, the carborundum problems having been com-

pletely solved and the opening of a market well started, Acheson turned his attention to the manufacture of graphite from amorphous carbon. In the manufacture of carborundum, some of that material was occasionally decompsed, owing to excessively high temperatures, and he noticed that a fine flake graphite was left as a result of the decomposition. Carborundum, or—to use its chemical name—silicon carbide, containing equal atomic proportions of the two elements of which it was composed, Acheson recognized that by heat they could be separated, the silicon volatilizing and the carbon secured as graphite. He took out patents protecting this method of manufacturing graphite, and after some further experimenting entered upon its commercial manufacture. A stock company was formed, called the Acheson Graphite Co., which was later absorbed by a new organization, the International Acheson Graphite Co. In 1891 this company produced about 2,500,000 pounds of graphite, of which 1,100,000 pounds were in the form of graphite electrodes. These electrodes have proved of great assistance in the development of electrochemical industries, as graphite in this form has been found to give excellent results.

Too much credit cannot be given the man who with so much self-sacrifice and perseverance built up these two industries to their present substantial footings. Although he met with many failures and disappointments, he was at no time discouraged and always took up the work with renewed determination.

Mr. Acheson has received several medals for his work, among which may be mentioned the following: Two medals from the Franklin Institute—one being for carborundum and the other for graphite; a gold medal from the World's Columbian Exposition, for carborundum; a gold medal from the Trans-Continental Exposition at Omaha, for carborundum and graphite; a gold medal from the Pan-American Exposition, at Buffalo, for the same; and a grand prix at Paris Exposition, 1900, for an exhibit of carborundum and graphite.

Mr. Acheson is a member of the American Institute of Electrical Engineers; American Association for the Advancement of Science, and a manager of the American Electrochemical Society.

## LOW TEMPERATURE RESEARCHES.*

By JAMES DEWAR,

*President of the British Association for the Advancement of Science*

### HISTORY OF THE RESEARCHES ON THE ABSOLUTE ZERO POINT OF TEMPERATURE.

THE nature of heat and cold must have engaged thinking men from the very earliest dawn of speculation upon the external world, but it will suffice for the present purpose if, disregarding ancient philosophers, and even mediæval alchemists, we take up the subject where it stood after the great revival of learning, and as it was regarded by the father of the inductive method. That this was an especially attractive subject to Bacon is evident from the frequency with which he recurs to it in his different works, always with lamentation over the inadequacy of the means at disposal for obtaining a considerable degree of cold. The great Robert Boyle was the first experimentalist who followed up Bacon's suggestion. In 1682 Boyle read a paper to the Royal Society on "New Experiments and Observations Touching Cold, or an Experimental History of Cold," published two years later in a separate work. This is really a most complete history of everything known about cold up to that date, but its great merit is the inclusion of numerous experiments made by Boyle himself on frigorific mixtures and the general effects of such upon matter. The agency chiefly used by Boyle in the conduct of his experiments was the glaciating mixture of snow or ice and salt. In the course of his experiment he made many important observations. Thus he observed that the salts which did not help the snow or ice to dissolve faster gave no effective freezing. He showed that water in becoming ice expands by about one-ninth of its volume and bursts gun barrels. He attempted to counteract the expansion and prevent freezing by completely filling a strong iron ball with water before cooling, anticipating that it might burst the bottle by the stupendous forces of expansion, or that if it did not, then the ice produced might, under the circumstances, be heavier than water. He speculated in an ingenious way on the change of water into ice Thus he says: "If cold be but a privation of heat through the recess of that ethereal substance which agitated the little eel-like particles of the water, and thereby made them compose a fluid body, it may easily be conceived that they should remain rigid in the postures in which the ethereal substances quitted them, and thereby compose an unfluid body like ice. Yet how these little eels should by that recess acquire as strong an endeavor outwards, as if they were so many little springs, and expand themselves with so stupendous a force, is that which does not so readily appear." The greatest degree of adventitious cold Boyle was able to produce did not make air exposed to its action lose a full tenth of its own volume, so that, in his own words, the cold does not "weaken the spring by anything near so considerable as one would expect." After making this remarkable observation and commenting upon its unexpected nature, it is strange Boyle did not follow it up He questions the existence of a body of its own nature supremely cold, by participating in which all other bodies obtain that quality, although the doctrine of a *primum frigidum* had been accepted by many sects of philosophers. The whole elaborate investigation cost Boyle immense labor, and he confesses that he "never handled any part of natural philosophy that was so troublesome and full of hardships." He looked upon his results but as a "beginning" in this field of inquiry. After the masterly essay of Boyle, the attention of investigators was chiefly directed to improving thermometrical instruments. The old air thermometer of Galileo being inconvenient to use, the introduction of fluid thermometers greatly aided the inquiry into the action of heat and cold. For a time great difficulty was encountered in selecting proper fixed points on the scales of such instruments, and this stimulated men like Huygens, Newton, Hooke and Amontons to suggest remedies and to conduct experiments. By the beginning of the eighteenth century the freezing point and the boiling point of water were agreed upon as fixed points, and the only apparent difficulties to be overcome were the selection of the fluid, accurate calibration of the capillary tube of the thermometer and a general understanding as to scale divisions. It must be confessed that great confusion and inaccuracy in temperature observations arose from the variety and crudeness of the instruments. This led Amontons, in 1702-1703, to contribute two papers to the French Academy which reveal great originality in the handling of the subject, and which, strange to say, are not generally known The first discourse deals with some new properties of the air and the means of accurately ascertaining the temperature in any climate. He regarded heat as due to a movement of the particles of bodies, though he did not in any way specify the nature of the motion involved; and as the general cause of all terrestrial motion, so that in its absence the earth would be without movement in its smallest parts. The new facts he records are observations on the pressure of air brought about by the action of heat. He shows that the ratio of the total pressure of air at two definite and steady temperatures and at constant volume is a constant, independent of the mass or the initial pressure of the air in thermometer. These results led to the increased perfection of the air thermometer as a standard instrument, Amontons' idea being to express the tempera-

* Presidential Address, delivered at the recent Belfast meeting of the British Association for the Advancement of Science (Lack of space requires the omission of the introductory remarks of the address; the historical notes in the chapter on the "History of the Researches on the Absolute Zero Point of Temperature" have also been slightly abridged. —Ed.)

ture of any locality in fractions of the degree of heat of boiling water. The great novelty of the instrument is that temperature is defined by the measurement of the length of a column of mercury. In passing, he remarks that we do not know the extreme of heat and cold. In the following year Amontons contributed to the Academy a further paper extending the scope of the inquiry. He there pointed out more explicitly that as the degrees of heat in his thermometer are registered by the height of a column of mercury, which the heat is able to sustain by the pressure or "spring" of the air, it follows that the extreme cold of the thermometer will be that which reduces the air to have no power of spring. This, he says, will be a much greater cold than what we call "very cold," because experiments have shown that if the "spring" of the air at boiling point is 73 inches, the degree of heat which remains in the air when brought to the freezing point of water is still very great, for it can still maintain the spring of 51½ inches. The greatest climatic cold on the scale of units adopted by Amontons is marked 50, and the greatest summer heat is 58, the value for boiling water being 73 and the zero being 52 units below the freezing point. Thus Amontons was the first to recognize that the use of air as a thermometric substance led to the inference of the existence of a zero of temperature, and his scale is nothing else than the absolute one we are now so familiar with. If we adopt the Celsius scale of temperature, then the zero of Amontons' air thermometer is *minus* 240 degrees. This is a remarkable approximation to our modern value for the same point of *minus* 273 degrees. It has to be confessed that Amontons' valuable contributions to knowledge met with that fate which has so often for a time overtaken the work of too-advanced discoverers. In other words, it was simply ignored, or, in any case, not appreciated by the scientific world, either of that time or half a century later. It is not till Lambert, in his work on "Pyrometrie," published in 1779, repeated Amontons' experiments and indorsed his results that we find any further reference to the absolute scale or the zero of temperature. Lambert's observations were made with the greatest care and refinement, and resulted in correcting the value of the zero of the air scale to *minus* 270 degrees, as compared with Amontons' *minus* 240 degrees. Lambert points out that the degree of temperature which is equal to zero is what one may call absolute cold, and that at this temperature the volume of the air would be practically nothing. In other words, the particles of the air would fall together and touch each other and become dense like water; and from this it may be inferred that the gaseous condition is caused by heat. Lambert says that Amontons' discoveries had found few adherents, because they were too beautiful and advanced for the time in which he lived.

About this time a remarkable observation was made by Professor Braun at Moscow, who, during the severe winter of 1759, succeeded in freezing mercury by the use of a mixture of snow and nitric acid. When we remember that mercury was regarded as quite a peculiar substance, possessed of the essential quality of fluidity, we can easily understand the universal interest created by the experiment of Braun. This was accentuated by the observations he made on the temperature given by the mercury thermometer, which appeared to record a temperature as low as *minus* 200° C. The experiments were soon repeated by Hutchins at Hudson's Bay, who conducted his work with the aid of suggestions given him by Cavendish and Black. The result of the new observations was to show that the freezing point of mercury is only *minus* 40° C., the errors in former experiments having been due to the great contraction of the mercury in the thermometer in passing into the solid state. From this it followed that the enormous natural and artificial colds which had generally been believed in had no proved existence. Still the possible existence of a zero of temperature very different from that deduced from gas thermometry had the support of such distinguished names as those of Laplace and Lavoisier. In their great memoir on "Heat," after making what they consider reasonable hypotheses as to the relation between specific heat and total heat, they calculate values for the zero, which range from 1,500° to 3,000° below melting ice. On the whole, they regard the absolute zero as being in any case 600° below the freezing point. Lavoisier, in his "Elements of Chemistry," published in 1792, goes further in the direction of indefinitely lowering the zero of temperature. Even as late as the beginning of the nineteenth century we find Dalton, in his new system of "Chemical Philosophy," adopting finally as the natural zero of temperature *minus* 3,000° C.

In Black's lectures we find that he takes a very cautious view with regard to the zero of temperature, but, as usual, is admirably clear with regard to its exposition. Thus he says: "We are ignorant of the lowest possible degree or beginning of heat. Some ingenious attempts have been made to estimate what it may be, but they have not proved satisfactory. Our knowledge of the degrees of heat may be compared to what we should have of a chain, the two ends of which were hidden from us and the middle only exposed to our view. We might put distinct marks on some of the links, and number the rest according as they are nearest to or further removed from the principal links. But, not knowing the distance of any links from the end of the chain, we could not compare them together with respect to their distance or say that one link was twice as far from the end of the chain as another." It is interesting to observe, however, that Black was evidently well acquainted with the work of Amontons, and strongly supports his inference as to the nature of air. Black's own special contribution to low-temperature studies was his explanation of the interaction of mixtures of ice with salts and acids by applying the doctrine of the latent heat of fluidity of ice to account for the frigorific effect. In a similar way Black explained the origin of the cold produced in Cullen's remarkable experiment of the evaporation of ether under the receiver of an air pump by pointing out that the latent heat of vaporization in this case necessitated such a result. Thus, by applying his own discoveries of latent heat, Black gave an intelligent explanation of the cause of all the low-temperature phenomena known in his day.

After the gaseous laws had been definitely formulated by Gay-Lussac and Dalton, the question of the absolute zero of temperature, as deduced from the properties of gases, was revived by Clement and Desormes. These distinguished investigators presented a paper on the subject to the French Academy in 1812, which, it appears, was rejected by that body. The authors subsequently elected to publish it in 1819. Relying on what we know now to have been a faulty hypothesis, they deduced from observations on the heating of air rushing into a vacuum the temperature of *minus* 267 degrees as that of the absolute zero. They further endeavored to show, by extending to lower temperatures the volume or the pressure coefficients of gases given by Gay-Lussac, that at the same temperature of *minus* 267 degrees the gases would contract so as to possess no appreciable volume, or, alternately, if the pressure was under consideration, it would become so small as to be non-existent. Although full reference is given to previous work bearing on the same subject, yet, curiously enough, no mention is made of the name of Amontons. It certainly gave remarkable support to Amontons' notion of the zero to find that simple gases like hydrogen and compound gases like ammonia, hydrochloric, carbonic and sulphurous acids should all point to substantially the same value for this temperature. But the most curious fact about this research of Clement and Desormes is that Gay-Lussac was a bitter opponent of the validity of the inferences they drew either from his work or their own. The mode in which Gay-Lussac regarded the subject may be succinctly put as follows: A quick compression of air to one-fifth volume raises its temperature to 300 degrees, and if this could be made much greater and instantaneous the temperature might rise to 1,000 or 2,000 degrees. Conversely,

if air under five atmospheres were suddenly dilated, it would absorb as much heat as it had evolved during compression, and its temperature would be lowered by 300 degrees. Therefore, if air were taken and compressed to 50 atmospheres or more, the cold produced by its sudden expansion would have no limit. In order to meet this position, Clement and Desormes adopted the following reasoning: They pointed out that it had not been proved that Gay-Lussac was correct in his hypothesis, but that in any case it tacitly involves the assumption that a limited quantity of matter possesses an unlimited supply of heat. If this were the case, then heat would beb unlike any other measurable thing or quality. We know now that Gay-Lussac was wrong in supposing the increment of temperature arising from a given gaseous compression would produce a corresponding decrement from an identical expansion. After this time the zero of temperature was generally recognized as a fixed ideal point, but, in order to show that it was hypothetical, a distinction was drawn between the use of the expressions, zero of absolute temperature and the absolute zero.

The whole question took an entirely new form when Lord Kelvin, in 1848, after the mechanical equivalent of heat had been determined by Joule, drew attention to the great principles underlying Carnot's work on the "Motive Power of Heat," and applied them to an absolute method of temperature measurement, which is completely independent of the properties of any particular substance. The principle was that for a difference of one degree on this scale, between the temperatures of the source and refrigerator, a perfect engine should give the same amount of work in every part of the scale. Taking the same fixed points as for the Centigrade scale, and making 100 of the new degrees cover that range, it was found that the degrees not only within that range, but as far beyond as experimental data supplied the means of comparison, differed by only minute quantities from those of Regnault's air thermometer. The zero of the new scale had to be determined by the consideration that when the refrigerator was at the zero of temperature the perfect engine should give an amount of work equal to the full mechanical equivalent of the heat taken up. This led to a zero of 273 degrees below the temperature of freezing water, substantially the same as that deduced from a study of the gaseous state. It was a great advance to demonstrate by the application of the laws of thermodynamics not only that the zero of temperature is a reality, but that it must be located at 273 degrees below the freezing point of water. As no one has attempted to impugn the solid foundation of theory and experiment on which Lord Kelvin based his thermodynamic scale, the existence of a definite zero of temperaturre must be acknowledged as a fundamental scientific fact.

### LIQUEFACTION OF GASES AND CONTINUITY OF STATE.

In these speculations, however, chemists were dealing theoretically with temperatures to which they could not make any but the most distant experimental approach. Cullen, the teacher of Black, had indeed shown how to lower temperature by the evaporation of volatile bodies, such as ether, by the aid of the air pump; and the later experiments of Leslie and Wollaston extended the same principle. Davy and Faraday made the most of the means at command in liquefying the more condensable gases, while at the same time Davy pointed out that they in turn might be utilized to procure greater cold by their rapid reconversion into the aeriform state. Still, the chemist was sorely hampered by the want of some powerful and accessible agent for the production of temperatures much lower than had ever been attained. That want was supplied by Thilorier, who in 1835 produced liquid carbonic acid in large quantities, and further made the fortunate discovery that the liquid could be frozen into a snow by its own evaporation. Faraday was prompt to take advantage of this new and potent agent. Under exhaustion he lowered its boiling point from *minus* 78° C. to *minus* 110° C., and, by combining this low temperature with pressure, all the gases were liquefied by the year 1844, with the exception of the three elementary gases—hydrogen, nitrogen and oxygen—and three compound gases—carbonic oxide, marsh gas and nitric oxide. Andrews, some twenty-five years after the work of Faraday, attempted to induce change of state in the uncondensed gases by using much higher pressures than Faraday employed. Combining the temperature of a solid carbonic acid bath with pressures of 300 atmospheres, Andrews found that none of these gases exhibited any appearance of liquefaction in such high states of condensation. But, so far as change of volume by high compression went, Andrews confirmed the earlier work of Natterer by showing that the gases become proportionately less compressible with growing pressure. While such investigations were proceeding, Regnault and Magnus had completed their refined investigations on the laws of Boyle and Gay-Loussac. A very important series of experiments were made by Joule and Kelvin "On the Thermal Effects of Fluids in Motion," about 1862, in which the thermometrical effects of passing gases under compression through porous plugs furnished important data for the study of the mutual action of the gas molecules. No one, however, had attempted to make a complete study of a liquefiable gas throughout wide ranges of temperature. This was accomplished by Andrews in 1869, and his Bakerian lecture "On the Continuity of the Gaseous and Liquid States of Matter" will always be regarded as an epoch-making investigation. During the course of this research Andrews observed that liquid carbonic acid raised to a temperature of 31° C. lost the sharp concave surface of demarcation between the liquid and the gas, the space being now occupied by a homogeneous fluid, which exhibited, when the pressure was suddenly diminished or the temperature slightly lowered, a peculiar appearance of moving or flickering striæ, due to great local alterations of density. At temperatures above 31° C. the separation into two distinct kinds of matter could not be effected, even when the pressure reached 400 atmospheres. This limiting temperature of the change of state from gas to liquid Andrews called the critical temperature. He showed that this temperature is constant, and differs with each substance, and that it is always associated with a definite pressure peculiar to each body. Thus the two constants, critical temperature and pressure, which have been of the greatest importance in subsequent investigations, came to be defined, and a complete experimental proof was given that "the gaseous and liquid states are only distinct stages of the same condition of matter and are capable of passing into one another by a process of continuous change."

In 1873 an essay "On the Continuity of the Gaseous and Liquid State," full of new and suggestive ideas, was published by van der Waals, who, recognizing the value of Clausius' new conception of the virial in dynamics, for a long-continued series of motions, either oscillatory or changing exceedingly slow with time, applied it to the consideration of the molecular movements of the particles of the gaseous substance and, after much refined investigation and the fullest experimental calculation available at the time, devised his well-known equation of continuity. Its paramount merit is that it is based entirely on a mechanical foundation, and is in no sense empiric, we may therefore look upon it as having a secure foundation in fact, but also as being capable of extension and improvement. James Thomson, realizing that the straight-line breach of continuous curvature in the Andrews isothermals was untenable to the physical mind, propounded his emendation of the Andrews curves, namely, that they were continuous and of S form. We also owe to James Thomson the conception and execution of a three-dimensional model of Andrews' results, which has been of the greatest service in exhibiting the three variables by means of a specific surface, afterwards greatly extended and developed by Prof. Willard Gibbs. The suggestive work of James Thomson undoubtedly was a valuable aid to van der Waals, for, as soon as he reached the point where his equation had to show the continuity of the two states,

was the first difficulty he had to encounter, and he succeeded in giving the explanation. He also gave a satisfactory reason for the existence of a minimum value of the product of volume and pressure in the Regnault isothermals. His isothermals, with James Thomson's completion of them, were now shown to be the results of the laws of dynamics. Andrews applied the new equation to the consideration of the coefficients of expansion with temperature and of pressure with temperature, showing that although they were nearly equal, nevertheless they were almost independent quantities. His investigation of the capillarity constant was masterly, and he added further to our knowledge of the magnitudes of the molecules of gases and of their mean free paths. Following up the experiments of Joule and Kelvin, he showed how their cooling coefficients could be deduced, and proved that they vanished at a temperature in each case, which is a constant multiple of the specific critical temperature. The equation of continuity developed by van der Waals involved the use of three constants instead of one, as in the old law of Boyle and Charles, the latter being only utilized to express the relation of temperature, pressure and volume, when the gas is far removed from its point of liquefaction. Of the two new constants, one represents the molecular pressure arising from the attraction between the molecules, the other four times the volume of the molecules. Given these constants of a gas, van der Waals showed that his equation not only fitted into the general characters of the isothermals, but also gave the values of the critical temperature, the critical pressure and the critical volume. In the case of carbonic acid, the theoretical results were found to be in remarkable agreement with the experimental values of Andrews. This gave chemists the means of ascertaining the critical constants, provided sufficiently accurate data derived from the study of a few properly-distributed isothermals of the gaseous substance were available. Such important data came into the possession of chemists when Amagat published his valuable paper on "The Isothermals of Hydrogen, Nitrogen, Oxygen, Ethylene," etc., in the year 1880. It now became possible to calculate the critical data with comparative accuracy for the so-called permanent gases oxygen and nitrogen, and this was done by Sarrau in 1882. In the meantime a great impulse had been given to a further attack upon the so-called permanent gases by the suggestive experiments made by Pictet and Cailletet. The static liquefaction of oxygen was effected by Wroblewski in 1883, and thereby the theoretical conclusions derived from van der Waals' equation were substantially confirmed. The liquefaction of oxygen and air was achieved through the use of liquid ethylene as a cooling agent, which enabled a temperature of *minus* 140 degrees to be maintained by its steady evaporation *in vacuo*. From this time liquid oxygen and air came to be regarded as the potential cooling agents for future research, commanding as they did a temperature of 200 degrees below melting ice. The theoretical side of the question received at the hands of van der Waals a second contribution, which was even more important than his original essay, and that was his novel and ingenious development of what he calls "The Theory of Corresponding States." He defined the corresponding states of two substances as those in which the ratios of the temperature, pressure and volume to the critical temperature, pressure and volume respectively were the same for the two substances, and in corresponding states he showed that the three pairs of ratios all coincided. From this a series of remarkable propositions were developed, some new, some proving previous laws that were hitherto only empiric and some completing and correcting faulty, though approximate, laws. As examples, he succeeded in calculating the boiling point of carbonic acid from observations on ether vapor, proved Kopp's law of molecular volumes and showed that at corresponding temperatures the molecular latent heats of vaporization are proportional to the absolute critical temperature, and that under the same conditions the coefficients of liquid expansion are inversely proportional to the absolute critical temperature and that the coefficients of liquid compressibility are inversely proportional to the critical pressure. All these propositions and deductions are in the main correct, though further experimental investigation has shown minor discrepancies requiring explanation. Various proposals have been made to supplement van der Waals' equation so as to bring it into line with experiments, some being entirely empiric, others theoretical. Clausius, Sarrau, Wroblewski, Batteli and others attacked the question empirically, and in the main preserved the co-volume (depending on the total volume of the molecules) unaltered while trying to modify the constant of molecular attraction. Their success depended entirely on the fact that, instead of limiting the number of constants to three, some of them have increased them to as many as ten. On the other hand, a series of very remarkable theoretical investigations have been made by van der Waals himself, by Kammerlingh Onnes, Korteweg, Jaeger, Boltzmann, Dieterici and Rienganum and others, all directed in the main towards an admitted variation in the value of the co-volume, while preserving the molecular attraction constant. The theoretical deductions of Tait lead to the conclusion that a substance below its critical point ought to have two different equations of the van der Waals type, one referring to the liquid and the other to the gaseous phase. One important fact was soon elicited, namely, that the law of correspondence demanded only that the equation should contain not more than three constants for each body. The simplest extension is that made by Reinganum, in which he increased the pressure for a given mean kinetic energy of the particles inversely in the ratio of the diminution of free volume, due to the molecules possessing linear extension. Berthelot has shown how a "reduced" isothermal may be got by taking two other prominent points as units of measurement instead of the critical co-ordinates. The most suggestive advance in the improvement of the van der Waals equation has been made by a lady, Mme. Christine Meyer. The idea at the base of this new development may be understood from the following general statement: van der Waals brings the van der Waals surfaces for all substances into coincidence at the point where volume, pressure and temperature are nothing, and then stretches or compresses all the surfaces parallel to the three axes of volume, pressure and temperature until their critical points coincide. But on this plan the surfaces do not quite coincide, because the points where the three variables are respectively nothing are not corresponding points. Mme. Meyer's plan is to bring all the critical points first into coincidence, and then to compress or extend all the representative surfaces parallel to the three axes of volume, pressure and temperature until the surfaces coincide. In this way, taking 29 different substances, she completely verifies from experiment van der Waals' law of correspondence. The theory of van der Waals has been one of the greatest importance in directing experimental investigation and in attacking the difficult problems of the liquefaction of the most permanent gases. One of its greatest triumphs has been the proof that the critical constants and the boiling point of hydrogen theoretically deduced by Wroblewski from a study of the isothermals of the gas taken far above the temperature of liquefaction are remarkably near the experimental values. We may safely infer, therefore, that if hereafter a gas be discovered in small quantity, even four times more volatile than liquid hydrogen, yet by a study of its isothermals at low temperature we shall succeed in finding its most important liquid constants, although the isolation of the real liquid may for the time be impossible. It is perhaps not too much to say that as a prolific source of knowledge in the department dealing with the continuity of state in matter it would be necessary to go back to Carnot's cycle to find a proposition of greater importance than the theory of van der Waals and his development of the law of corresponding states.

It will be apparent from what has just been said that, thanks to the labors of Andrews, van der Waals and others, theory

had again far outrun experiment. We could calculate the constants and predict some of the simple physical characteristics of liquid oxygen, hydrogen or nitrogen with a high degree of confidence long before any one of the three had been obtained in the static liquid condition permitting of the experimental verification of the theory. This was the more tantalizing, because, with whatever confidence the chemist may anticipate the substantial corroboration of his theory, he also anticipates, with almost equal conviction, that as he approaches more and more nearly to the zero of absolute temperature he will encounter phenomena compelling modification, revision and refinement of formulas which fairly covered the facts previously known. Just as nearly seventy years ago chemists were waiting for some means of getting a temperature of 100 degrees below melting ice, so ten years ago they were casting about for the means of going 100 degrees lower still. The difficulty, it need hardly be said, increases in a geometrical rather than in an arithmetical ratio. Its magnitude may be estimated from the fact that to produce liquid air in the atmosphere of an ordinary laboratory is a feat analogous to the production of liquid water starting from steam at a white heat and working with all the implements and surroundings at the same high temperature. The problem was not so much how to produce intense cold, as how to save it when produced from being immediately leveled up by the relatively superheated surroundings. Ordinary non-conducting packings were inadmissible, because they are both cumbrous and opaque, while in working near the limits of our resources it is essential that the product should be visible and readily handled. It was while puzzling over this mechanical and manipulative difficulty in 1892 that it occurred to me that the principle of an arrangement used nearly twenty years before in some calorimetric experiments, which was based upon the work of Dulong and Petit on radiation, might be employed with advantage, as well as to protect cold substances from heat as hot ones from rapid cooling. I therefore tried the effect of keeping liquefied gases in vessels having a double wall, the annular space between being very highly exhausted. Experiments showed that liquid air evaporated at only one-fifth of the rate prevailing when it was placed in a similar unexhausted vessel, owing to the convective transference of heat by the gas particles being enormously reduced by the high vacuum. But, in addition, these vessels lend themselves to an arrangement by which radiant heat can also be cut off. It was found that when the inner walls were coated with a bright deposit of silver the influx of heat was diminished to one-sixth the amount entering without the metallic coating. The total effect of the high vacuum and the silvering is to reduce the ingoing heat to about 3 per cent. The efficiency of such vessels depends upon getting as high a vacuum as possible, and cold is one of the best means of effecting the desired exhaustion. All that is necessary is to fill completely the space that has to be exhausted with an easily-condensable vapor, and then to freeze it out in a receptacle attached to the primary vessel that can be sealed off. The advantage of this method is that no air pump is required, and that theoretically there is no limit to the degree of exhaustion that can be obtained. The action is rapid, provided liquid air is the cooling agent, and vapors like mercury, water or benzol are employed. It is obvious that when we have to deal with such an exceptionally volatile liquid as hydrogen the vapor filling may be omitted, because air itself is now an easily-condensable vapor. In other words, liquid hydrogen, collected in such vessels with the annular space full of air, immediately solidifies the air, and thereby surrounds itself with a high vacuum. In the same way, when it shall be possible to collect a liquid boiling on the absolute scale at about 5 degrees, as compared with the 20 degrees of hydrogen, then you might have the annular space filled with the latter gas to begin with, and yet get directly a very high vacuum, owing to the solidification of the hydrogen. Many combinations of vacuum vessels can be arranged, and the lower the temperature at which we have to operate the more useful they become. Vessels of this kind are now in general use, and in them liquid air has crossed the American continent. Of the various forms, that variety is of special importance which has a spiral tube joining the bottom part of the walls, so that any liquid gas may be drawn off from the interior of such a vessel. In the working of regenerative coils such a device becomes all-important, and such special vessels cannot be dispensed with for the liquefaction of hydrogen.

In the early experiments of Pictet and Cailletet cooling was produced by the sudden expansion of the highly-compressed gas, preferably at a low temperature, the former using a jet that lasted for some time, the latter an instantaneous adiabatic expansion in a strong glass tube. Neither process was practicable as a mode of producing liquid gases, but both gave valuable indications of partial change into the liquid state by the production of a temporary mist. Linde, however, saw that the continuous use of a jet of highly-compressed gas, combined with regenerative cooling, must lead to liquefaction on account of what is called the Kelvin-Joule effect: and he succeeded in making a machine, based on this principle, capable of producing liquid air for industrial purposes. These experiments had proved that, owing to molecular attraction, compressed gases passing through a porous plug or small aperture were lowered in temperature by an amount depending on the difference of pressure, and inversely as the square of the absolute temperature. This means that for a steady difference of pressure the cooling is greater the lower the temperature. The only gas that did not show cooling under such conditions was hydrogen. Instead of being cooled, it became actually hotter. The reason for this apparent anomaly in the Kelvin-Joule effect is that every gas has a thermometric point of inversion above which it is heated, and below which it is cooled. This inversion point, according to van der Waals, is six and three-quarter times the critical point. The efficiency of the Linde process depends on working with highly-compressed gas well below the inversion temperature, and in this respect this point may be said to take the place of the critical one, when in the ordinary way direct liquefaction is being effected by the use of specific liquid cooling agents. The success of both processes depends upon working with a certain temperature range, only the Linde method gives us a much wider range of temperature within which liquefaction can be effected. This is not the case if, instead of depending on getting cooling by the internal work done by the attraction of the gas molecules, we force the compressed gas to do external work, as in the well-known air machines of Kirk and Coleman. Both these inventors have pointed out that there is no limit of temperature, short of liquefaction of the gas in use in the circuit, that such machines are not capable of giving. While it is theoretically clear that such machines ought to be capable of maintaining the lowest temperatures, and that with the least expenditure of power, it is a very different matter to overcome the practical difficulties of working such machines under the conditions. Coleman kept a machine delivering air at *minus* 83 degrees for hours, but he did not carry his experiments any further. Recently Monsieur Claude, of Paris, has, however, succeeded in working a machine of this type so efficiently that he has managed to produce one liter of liquid air per horse-power expended per hour in the running of the engine. This output is twice as good as that given by the Linde machine, and there is no reason to doubt that the yield will be still further improved. It is clear, therefore, that in the immediate future the production of liquid air and hydrogen will be effected most economically by the use of machines producing cold by the expenditure of mechanical work.

### LIQUID HYDROGEN AND HELIUM.

To the physicist the copious production of liquid air by the methods described was of peculiar interest and value as affording the means of attacking the far more difficult problem of the liquefaction of hydrogen, and even as encouraging the hope that liquid hydrogen might in time be employed for the liquefaction of yet more volatile elements, apart from the importance

which its liquefaction must hold in the process of the steady advance towards the absolute zero. Hydrogen is an element of especial interest, because the study of its properties and chemical relations led great chemists like Faraday, Dumas, Daniell, Graham and Andrews to entertain the view that if it could ever be brought into the state of liquid or solid it would reveal metallic characters. Looking to the special chemical relations of the combined hydrogen in water, alkaline oxides, acids and salts, together with the behavior of these substances on electrolysis, we are forced to conclude that hydrogen behaves as the analogue of a metal. After the beautiful discovery of Graham that palladium can absorb some hundreds of times its own volume of hydrogen, and still retain its luster and general metallic character, the impression that hydrogen was probably a member of the metallic group became very general. The only chemist who adopted another view was my distinguished predecessor, Professor Odling. In his "Manual of Chemistry," published in 1861, he pointed out that hydrogen has chlorous as well as basic relations, and that they are as decided, important and frequent as its other relations. From such considerations he arrived at the conclusion that hydrogen is essentially a neutral or intermediate body, and therefore we should not expect to find liquid or solid hydrogen possess the appearance of a metal. This extraordinary prevision, so characteristic of Odling, was proved to be correct some thirty-seven years after it was made. Another curious anticipation was made by Dumas in a letter addressed to Pictet, in which he says that the metal most analogous to hydrogen is magnesium, and that probably both elements have the same atomic volume, so that the density of hydrogen, for this reason, would be about the value elicited by subsequent experiments. Later on, in 1872, when Newlands began to arrange the elements in periodic groups, he regarded hydrogen as the lowest member of the chlorine family; but Mendeleef, in his later classification, placed hydrogen in the group of the alkaline metals. On the other hand, Dr. Johnstone Stoney classes hydrogen with the alkaline earth metals and magnesium. From this speculative divergency it is clear no definite conclusion could be reached regarding the physical properties of liquid or solid hydrogen, and the only way to arrive at the truth was to prosecute low-temperature research until success attended the efforts to produce its liquefaction. This result I definitely obtained in 1898. The case of liquid hydrogen is, in fact, an excellent illustration of the truth already referred to, that no theoretical forecast, however apparently justified by analogy, can be finally accepted as true until confirmed by actual experiment. Liquid hydrogen is a colorless, transparent body of extraordinary intrinsic interest. It has a clearly-defined surface; is easily seen; drops well, in spite of the fact that its surface tension is only the thirty-fifth part of that of water, or about one-fifth that of liquid air, and can be poured easily from vessel to vessel. The liquid does not conduct electricity, and, if anything, is slightly diamagnetic. Compared with an equal volume of liquid air, it requires only one-fifth the quantity of heat for vaporization. On the other hand, its specific heat is ten times that of liquid air or five times that of water. The coefficient of expansion of the fluid is remarkable, being about ten times that of gas. It is by far the lightest liquid known to exist, its density being only one-fourteenth that of water. The lightest liquid previously known was liquid marsh gas, which is six times heavier. The only solid which has so small density as to float upon its surface is a piece of pith wood. It is by far the coldest liquid known. At ordinary atmospheric pressure it boils at *minus* 252.5 degrees or 20.5 degrees absolute. The critical point of the liquid is about 29 degrees absolute, and the critical pressure not more than 15 atmospheres. The vapor of the hydrogen arising from the liquid has nearly the density of air; that is, it is 14 times that of the gas at the ordinary temperature. Reduction of the pressure by an air pump brings down the temperature to *minus* 258 degrees, when the liquid becomes a solid resembling frozen foam; and this, by further exhaustion, is cooled to *minus* 260 degrees, or 13 degrees absolute, which is the lowest steady temperature that has been reached. The solid may also be got in the form of a clear, transparent ice, melting at about 15 degrees absolute, under a pressure of 55 mm., possessing the unique density of one-eleventh that of water. Such cold involves the solidification of every gaseous substance but one that is at present definitely known to the chemist, and so liquid hydrogen introduces the investigator to a world of solid bodies. The contrast between this refrigerating substance and liquid air is most remarkable. On the removal of the loose plug of cotton wool used to cover the mouth of the vacuum vessel in which it is stored, the action is followed by a miniature snow storm of solid air, formed by the freezing of the atmosphere at the point where it comes into contact with the cold vapor rising from the liquid. This solid air falls into the vessel and accumulates as a white snow at the bottom of the liquid hydrogen. When the outside of an ordinary test tube is cooled by immersion in the liquid, it is soon observed to fill up with solid air; and if the tube be now lifted out a double effect is visible, for liquid air is produced both in the inside and on the outside of the tube—in the one case by the melting of the solid, and in the other by condensation from the atmosphere. A tuft of cotton wool soaked in the liquid and then held near the pole of a strong magnet is attracted, and it might be inferred therefrom that liquid hydrogen is a magnetic body. This, however, is not the case; the attraction is due neither to the cotton-wool nor to the hydrogen—which, indeed, evaporates almost as soon as the tuft is taken out of the liquid—but to the oxygen of the air, which is well known to be a magnetic body, frozen in the wool by the extreme cold.

[*To be concluded.*]

## PROF. ROWLAND'S PAPERS.

"Science" states that the volume containing the physical papers of the late Prof. Henry A. Rowland is now nearly ready for distribution to its subscribers. It has been edited under the direction of a committee consisting of President Remsen, Professor Welch and Professor Ames. In the book, which contains about 750 pages, are collected not alone Professor Rowland's strictly scientific papers and his public addresses, but also a detailed description of his ruling engine, with plates and photographs. The memorial address of Professor Mendenhall serves as a biographical sketch, which is accompanied by a portrait of Professor Rowland. The subjects treated in these papers cover a wide range. In heat there is the great memoir on the mechanical equivalent of heat, with several shorter articles on thermometers. In electricity and magnetism there are the fundamental researches on magnetization, on the magnetic effort of electrical connection, on the value of the ohm, on the theory and use of alternating currents, etc. In light there are the renowned discovery and theory of the concave grating and the long series of investigations made in the field of spectroscopy.

## OBITUARY.

John Hall Gladstone, D.Sc., Ph.D., F.R.S., died, on October 6th, in London. His name is best known in electrochemical circles, from the fact that some fifteen years ago he worked out, in conjunction with Dr. Tribe, the so-called double sulphate theory of the lead storage battery. This theory has since been repeatedly tested, and is now generally accepted, especially since Dolezalek's elaborate recent researches. Dr. Gladstone reached an age of seventy-five years.

The Institution of Electrical Engineers of Great Britain has accepted the invitation of the American Institute of Electrical Engineers to hold a joint meeting in 1904 in the United States.

# ANALYSIS OF CURRENT ELECTROCHEMICAL PATENTS.

BY GEORGE P. SCHOLL.

ELECTRIC FURNACES AND FURNACE PRODUCTS.

*Process of Manufacturing Calcium Carbide.* Isaiah L. Roberts, New York. Patent No. 708,921, September 9, 1902. Application filed March 18, 1897.

The process consists essentially in the substitution of finely-ground anthracite coal for coke in the mixture of raw materials for the carbide furnace. Coke, as a component of the mixture, is said to be objectionable for various reasons—principally because, on account of its low specific gravity, it tends to float on top of the melted carbide, and is therefore only partially converted into carbide. As a consequence, a kind of segregation manifests itself in the block of carbide produced, which will show itself in the variations of chemical composition. A further disadvantage is stated to be that finely-ground coke gives rise to clouds of dust, and on that account is extremely objectionable to the workmen. Anthracite coal is of a higher specific gravity than coke, and, moreover, it does not have that dust-forming tendency of coke. The carbide thus produced is said not to burn so readily upon its surface when it is removed from the furnace as the product obtained from coke, and an increased yield is also claimed. The proportion may be the same as ordinarily employed, but a somewhat less proportion of anthracite also works satisfactorily. As far as anthracite coal is concerned as a raw material in the manufacture of calcium carbide, it does not seem to be used in this country. In the practice of the Union Carbide Co., Niagara Falls, N. Y. (Richards, "Electrochemical Industries," 1902, p. 22), ground coke is used in connection with burnt lime, and this company control almost all the carbide production in America. In Europe, however, and especially in France, anthracite is already used in the manufacture of calcium carbide, as appears from a paper read by Gall, on the "Industry of Calcium Carbide in France," before the Fourth International Congress of Applied Chemistry, at Paris, 1900. He says: "Charcoal, coke and anthracite have been used industrially. . . . The manufacturers of calcium carbide have preferred to avail themselves of the anthracite, which England continues to furnish of excellent quality. The anthracites of the Alps are, unfortunately, too impure. It is, however, interesting to note the ingenious solution of the problem found by the Compagnie de Fives-Lille. The anthracites of Bosel (Tarentaire), where the works are situated, leave an ash consisting almost entirely of silica, and a method is used by the company which permits them to obtain a product of the highest interest for metallurgy, together with the carbide, namely, ferro silicon, remarkable specimens of which were exhibited at the exposition." As the application for the patent was made in March, 1897, it has taken more than five years to get it through the Patent Office. An industry like that of calcium carbide, which has made such rapid strides in the course of comparatively few years, could hardly be expected to wait that long for the suggestion of improvements.

*Carborundum Articles, and Process of Making Same.* Frank J. Tone, Niagara Falls, N. Y. Patent No. 709,808, September 23, 1902. Application filed January 2, 1901.

This patent is assigned to the Carborundum Co., of which the inventor is superintendent. It contains the description of a process for the utilization of the so-called amorphous carborundum, a by-product of the carborundum furnace, which is found in the carborundum furnace at the end of the operation, surrounding the core of crystalline carborundum, in a zone where the heat has not been sufficient to change it into the crystalline variety. It was customary to carefully separate it from the crystalline product and mix it with another charge of raw material. This amorphous carborundum is now, according to the patent, pressed into bricks, or other desired shapes, and subjected again to the action of the current, when it is changed into a crystalline mass of carborundum. It is claimed that in this way the bricks or other shapes, though very firm and coherent, are obtained in a considerably more porous condition than if they were molded directly out of crystalline carborundum, and are consequently more desirable for many purposes, as lining furnaces, fire boxes, etc., where they have to withstand sudden changes of temperature without cracking or disintegration. For purposes where still more porous articles are wanted, the inventor proposes to mold them from a mixture of carbon and silica in the proper proportions, and then subject them to the heat of the electric furnace, in order to convert them into carborundum, which product then is said to be more coherent and dense than the ordinary carborundum furnace product, but more porous and of less weight per volume than if it were made of compressed amorphous carborundum. For a porosity between these two grades, amorphous carborundum and a mixture of carbon and silica, as described, are mixed together in the desired proportions. It is also proposed to make such articles of carbide of boron, by molding them either directly from the amorphous material obtained in the manufacture of that carbide or from a mixture of carbon and boracic acid, and treating them in the same manner as described above. Whenever it is desired, a solution of a binding material, such as silicate of soda, glue, etc., may also be added to the mixture before compressing it, which material will be volatilized in the subsequent furnace operation. These bricks will no doubt be a valuable and welcome addition to the list of refractory materials at the disposal of the metallurgist.

*Apparatus and Processes for the Electrolytic Production of Metals and Compounds. Bleaching Apparatus.* Chauncey Cook Clark, Philadelphia, Pa. Patent No. 708,796, September 9, 1902. Application filed January 22, 1901.

The object of this invention is stated to be "an apparatus for the manufacture of bleaching material in an inclosed receptacle by electrolysis, to thereby prevent the escape of the valuable chlorine gas separated from the chloride of sodium, and assure its absorption by the inclosed liquid." The apparatus in which the electrolysis is carried out is, in appearance, almost identical with the one described by the same inventor in patent No. 706,529, of August 12, 1902, under the head of "Electrochemical Apparatus," noted on page 65, Vol. I, of this journal. The application for the present apparatus was filed on January 22, 1901, while the application for the one described in patent No. 706,529 was filed on September 20, 1901. As a consequence, the apparatus under consideration, the result of an earlier application, does not contain improvements in the mechanical construction which were embodied in the later application. All the objections which were raised to that apparatus, on page 63, Vol. I, of this journal, are applicable here. One statement is of interest, as showing how easy the problem of producing bleaching solutions is solved on paper. It is stated: "The separation being produced by a series of electrodes suspended in the salt solution, the residium comprising the impurities of the solution, as the earthy, saline, vegetable (!), animal (!), metallic matter, etc., falling to the bottom of the receptacle, where means are provided for its removal." It is a pity that the impurities cannot be so easily disposed of in the actual electrochemical practice in general, and the manufacture of bleaching solutions in particular. Instead of that, they seem to be most obstinately bent upon taking part in the decomposition and producing many undesired

and annoying complications, so that in most instances a preparatory chemical treatment of the electrolytes has to be resorted to in order to remove them.

*Electrolytically Treating Ores.* Clinton Emerson Dolbear, Boston, Mass. Patent No. 709,817, September 23, 1902. Application filed June 3, 1901.

This invention relates to "a new and improved method of producing from raw ores metallic copper or other metals by electrolysis in the wet way." The inventor describes his process as follows: "I take a body of the metal-bearing ore that is soluble in a dissolved nitrate or in nitric acid, crush it and subject it to the action of a nitrate in solution or to nitric acid mixed with sulphuric acid. The object of the nitrate or nitric acid is to furnish the nitric acid radical in quantity sufficient to accomplish the necessary chemical changes. An excess of nitric acid will not interfere with the working of the process. The sulphuric acid will not of itself attack the ore if it be in a state of sulphide or metallic copper, but in the presence of the nitric acid radical it will do so. If a nitrate be used—for instance, Chile niter (sodium nitrate)—the sulphuric acid takes the sodium from the nitrate, liberates the nitric acid radical which in its turn will attack the sulphide, dissolving the base. The sulphuric acid takes the metal from the nitric acid radical, forming the sulphate. During this process the nitric acid loses oxygen, forming nitric oxide, which, under usual conditions, will rise to the surface and be lost." The inventor then proposes to put an insoluble anode, carbon, for example, on the bottom of the electrolytic vat, stating that he can use also anodes of gold or platinum; but it is very probable that he will not use those in practice if he wants anybody to invest in his apparatus. The cathode is of the composition of the metal, to be "plated out" of the bath. The electrolytic operation is described as follows: "When current is flowing, the positive terminal will liberate oxygen, which, passing through the solution, oxydizes the nitric oxide back to nitric acid. This is then in a condition to take up more metal, react with the sulphuric acid and again go through the process just described. The current, of course, at the same time plates the metal onto the cathode, thereby in one operation giving the desired metal from the raw ore." As will be seen, it is proposed to utilize for the solution of the metallic constituents of the ore the well-known reaction used in the laboratory for the production of nitric oxide, which consists in treating copper turnings with a saturated solution of saltpeter, and then introducing concentrated sulphuric acid. The reaction takes place according to the equation:

$$3\,Cu + 2\,NaNO_3 + 4\,H_2SO_4 = 3\,CuSO_4 + Na_2SO_4 + 4\,H_2O + 2\,NO.$$

Theoretically, the reactions described as taking place in the solution and electrolysis are all possible, but, unfortunately, the reagents described will not only dissolve the principal metallic constituent of the ore, but also all the other metals present in it, a fact which the inventor unconsciously admits by claiming his process to be universally applicable to ores. If this is the case, the action of the current will not only result in "plating out" the one metal which the inventor desires to obtain, but will deposit all of them. This will be especially true in this case, as the mass of ore resting on the anodes, between the two electrodes, will of necessity increase the resistance of the solution to the passage of the current, and will prevent the application of the artifice of using a low enough voltage for decomposition f. i. in the case of copper ores, in order to deposit the copper only by keeping the voltage of the bath below the decomposition value of the salts of the other metals present. The problem of purification of the electrolyte, which seems to have been entirely neglected in the process under consideration, is a very serious one (see, for instance, the patent noted below of Tossisza). The use of nitrates as electrolytes is also more or less undesirable in practice, as they are not by any means as easily handled as the sulphates and chlorides. If the nitric acid electrolyte is not regenerated in the process, then it would be eo ipso inapplicable in practice, as the use of such an expensive reagent would be out of the question, a fact which is also emphasized by Schnabel in his "Hand-book of Metallurgy," in speaking about copper sulphide ores, where he says: "The energetic solvents, such as aqua regia, nitric acid, chlorine and hot concentrated sulphuric acid, are too dear to be applicable on a large scale." It would, moreover, seem as though a very fine crushing of the ores was necessary for the successful operation of a process like the one under consideration, a fact which would increase the cost of operation considerably. If this process has been noted in such detail, it has been done with a view of considering it as a representative of its class, bearing in mind that it is not always the theoretically most perfect process which gives the best results in practice.

*Electrometallurgic Treatment of Ores of Copper and Other Metals.* Constantin Jean Tossisza, Paris, France. Patent No. 710,346, September 30, 1902. Application filed August 6, 1901.

The inventor states that heretofore the direct electrolytic treatment with insoluble anodes of the solutions obtained by the action of sulphuric acid on previously roasted copper ores has been impracticable, because it required, before all, a complete purification of the solution obtained in order to free them from all sulphates other than the sulphate of copper. Such a purification being very difficult, the direct electrolytic treatment was, for that reason, industrially inapplicable. It is intended to overcome that difficulty by making use of the low voltage of decomposition of the copper sulphate. It is, however, very difficult in practice to maintain this low voltage of decomposition, on account of the polarization manifesting itself at the anode, and thus causing a rise of potential above the voltage of decomposition of the other salts present. Consequently the deposit, which was pure in the beginning, will be more and more contaminated with other metals as the electrolysis proceeds. The one thing to do, then, would be to prevent this polarization, and this the inventor proposes to do by introducing a depolarizer, for which he uses sulphurous acid. The anodes are made of carbon, and the sulphurous acid may be introduced either as solution or in the form of gas outside of the anode, or through the anode itself, for which purpose the anode is made hollow. The inventor says that he has ascertained that the transformation of the sulphurous acid into sulphuric acid at the anode gives rise to an electromotive force, which diminishes the necessary voltage and lowers it to two-tenths of a volt. "One can thus obtain a very beautiful deposit of pure electrolytic copper directly from an impure solution with a sufficient intensity at a voltage of about six-tenths of a volt," whereas in all processes heretofore known one could only obtain this electrolysis with insoluble anodes at voltages above 1 3-10 volts. The sulphurous acid which is used is preferably obtained from the preliminary treatment of the sulphite ores, which are roasted to produce oxides and sulphurous acid gas, which is used as such or in solution. The oxides of the metals produced are then dissolved in sulphuric acid and subjected to electrolysis. The idea of using sulphurous acid as a depolarizing agent in the deposition of copper is not new, as may be seen from Borcher's "Electro-Metallurgy," page 214, where it is stated that in Stolberg, Germany, sulphurous acid had been used for the same purpose, and that a patent for the same idea was already applied for in 1885.

*Electrolytic Decomposition of Alkaline Salts.* Edwin Edser and Meyer Wildermann, London, England. Patent No. 709,971, September 30, 1902. Application filed March 28, 1901.

This specification applies to the electrolysis of alkaline salts in those forms of apparatus in which mercury is used as a means of absorbing the alkali metal. The inventors claim that they are able to affect the decomposition of the alkali amalgam quicker than before by bringing it into contact with pieces of

carbon having part of their surface coated with a suitable electro-deposited metal.

STORAGE BATTERIES.

*Electric Accumulator Plate.* Alexander Fischer, Berlin, Germany. Patent No. 708,334, September 2, 1902.

This invention relates to improvements in electric accumulator plates, consisting of sheets of lead folded into serpentine form. The objects of the invention are, first, to stiffen the plates, and, secondly, to increase their active surface. In carrying out this invention, the sheets of lead which are to be converted into accumulator plates are bent or corrugated so as to produce a number of relatively deep parallel grooves, running from top to bottom of the plates. At the apex of each corrugation a number of tongues are cut out, thus producing openings for the passage of the electrolyte. Along the top and bottom edge of the plate bars are provided, in order to stiffen the plate laterally. The arrangement thus described constitutes the framework of the plates, which are then ready to be formed and filled with the active mass.

*Method of Manufacturing Secondary Battery Plates.* George H. Christian, Cleveland, Ohio. Patent No. 708,695, September 9, 1902. Application filed December 7, 1901.

The invention relates to the manufacture of secondary batteries, and is particularly applicable to the preparation of the spongy lead element of such batteries. The formation of the spongy lead from the peroxide is carried out either in an electrolyte composed of a solution of dilute sulphuric acid or plates provided with litharge or red lead are respectively caused to constitute the cathode and anode of an electrolytic cell, with an electrolyte consisting of dilute sulphuric acid. As a result of the electrolysis, the litharge is reduced to spongy lead, and the red lead changed to lead peroxide. Instead of conducting both these operations in an electrolyte composed of dilute sulphuric acid, the inventor substitutes an electrolyte consisting of a solution of an organic acid, such as oxalic or formic acid, or a compound of such acid with an alkaline "earth," such as oxalate of potassium, oxalate of sodium, etc. A solution of about one pound of oxalic acid in one gallon of water is used by preference. On passing the current, of preferably about $\frac{1}{2}$ ampère per square inch of plate surface, the peroxide is rapidly reduced to spongy lead. After the reduction is complete, the spongy lead plates are immersed in a bath of running water, where they are left for about twelve hours, in order to thoroughly remove the carbonic acid and oxalic acid remaining in the pores of the lead. The inventor states that by this means he has found that spongy lead plates having superior physical and electrical qualities, with less loss of active material, are produced, a wider variation in the qualities of the current used being permitted. These plates are also claimed to have a greater electrical capacity per pound of lead than other plates. It will be seen that the inventor proposes rather expensive electrolytes in place of the dilute sulphuric acid used heretofore.

*Method of Manufacturing Plates for Secondary Batteries.* George H. Christian, Cleveland, Ohio. Patent No. 708,694, September 9, 1902. Application filed December 7, 1901.

This specification is almost identical in phraseology with the preceding one by the same inventor. The only change is in the composition of the electrolyte, where, instead of a solution of oxalic acid and water, there is now substituted a solution of a compound of an organic acid with an alkaline "earth," such as oxalate of potassium, oxalate of sodium, etc., which oxalate is preferably prepared in solution with water. The same improvements as claimed above for oxalic acid alone are, of course, claimed in this specification for potassium and sodium oxalate. The first claim reads: "In the process of manufacturing plates for secondary batteries, the step which consists in electrolytically reducing an oxide of lead in an electrolytic cell having an electrolyte containing a compound of an organic reducing agent." This claim is certainly broad enough to satisfy any inventor.

*Jar for Storage Batteries.* Patrick Kennedy, Brooklyn, N. Y. Patent No. 709,157, September 16, 1902. Application filed January 6, 1902.

This application describes an improved form of receptacle or jar for the plates of storage batteries, which is especially applicable when the storage batteries are used in installations for the lighting of railway cars. The inventor provides a lining of soft vulcanized rubber, closely fitted into an outer receptacle, ordinarily made of wood. He also provides suitable protecting guards or buffers on the sides, which serve to keep the battery plates from contact with the lining. A ribbed plate of any suitable ceramic material is resting on the rubber lining on the bottom. It is claimed that this jar will withstand the jolting or shocks to which it may be subjected on the cars without rupture or cracking of the lining.

*Secondary Battery.* William L. Silvey, Dayton, Ohio. Patent No. 709,611, September 23, 1902. Application filed February 8, 1902.

This invention relates to the details whereby storage batteries may be more perfectly arranged, easier assembled and taken apart for repairs than has heretofore been possible. Any battery man of ordinary intelligence should be able to make his own repairs, and with but little necessary apparatus. It is proposed to accomplish this by doing away with the connecting bar welded to the battery plates and substitute therefor a slotted bar, to which the various plates are fastened by screw bolts. Various mechanical arrangements of the connecting bar are described at length. The greatest objection to an arrangement of this kind seems to lie in the multiplication of individual contact points, each of which is liable to get out of order, and will necessitate a great deal more watching than is necessary when the plates are welded to the connecting bar.

*Electric Separator for Batteries.* Arthur W. Harrison, Los Angeles, Cal. Patent No. 708,708, September 9, 1902. Application filed May 7, 1902.

The patent aims at providing an efficient separating medium for storage-battery plates, especially in batteries designed for use in automobiles, where it is desirable that the battery should be as light as possible, and that the electrodes should be kept perfectly insulated from each other. Corrugated sheet rubber or corrugated sheets of wood are both unsatisfactory. It is claimed that a plate separator made from yucca wood will furnish a very tough and light non-conducting separator, which permits a free circulation of the electrolyte and yet keeps the electrodes perfectly insulated from each other. The material, after being cut from the tree in the desired length and thickness, is treated by boiling it in a weak solution of sulphuric acid or caustic soda until the starch and other non-fibrous material is dissolved. It is then dried and ready for use. If the non-fibrous material is not removed, it is said to clog the circulation and interfere with the action of the battery.

*Electric Battery.* Timke Henry Klinker, Jr., and Richard Gabrielsky, Jersey City, N. J. Patent No. 710,278, September 30, 1902.

The cell described in this specification is one of the class of dry batteries. The positive electrode is formed of a sheet of zinc, constructed in such a way as to present as large a surface as possible. The negative electrode is composed of carbon, corrugated at its lower part, also in order to increase its surface. The cell is filled with sal ammoniac, which is used either alone or in combination with some other well-known material. Provision is also made for moistening the filling and thus "reactivating" the cell, by arranging conduits for that purpose in the carbon and zinc electrodes. The whole is inclosed in a casing of sheet lead, formed from one piece of material, without a seam.

MISCELLANEOUS.

*Process of Manufacturing Nitrogen Compounds from Atmospheric Nitrogen.* Charles T. Bradley and Dimmitt Ross Lovejoy, New York. Patent No. 709,867, September 30, 1902. Application filed March 19, 1900.

This patent describes the process for the manufacture of nitrogen compounds from atmospheric air evolved by Mr. Charles T. Bradley, the president, and Mr. D. R. Lovejoy, the electrician of the Atmospheric Products Co., Niagara Falls, N. Y., the works of which were described and illustrated in an article by Prof. J. W. Richards in this journal, Vol. I, pages 21 to 23. The process has proven so successful on an experimental scale that a large plant is to be built at Niagara Falls, part of which is already in process of erection. The inventors have found that the silent electric discharge is not capable of effecting nitrification to an appreciable amount, and that the ordinary spark is also of comparatively little value. In order to produce a large yield, an arc is absolutely necessary, and the best results are obtained by using a spark as thin as possible. The patent covers the process for the nitrification of air, describing also briefly the apparatus in which the nitrification is carried out. The various steps of the process are illustrated by a plan of the complete installation, as shown by Fig. 1. The atmospheric air enters into the systems of apparatus by the air inlet 58. The air entering the nitrification apparatus should be as dry as possible, in order to reduce the formation of any nitric acid in the apparatus itself to a minimum. This is said to be of advantage when the nitrous oxide and nitrogen

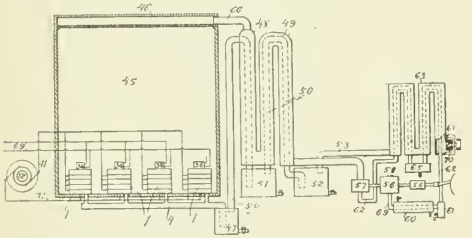


FIG. 1—FIXATION OF NITROGEN FROM THE AIR.

tetroxide are to be collected as such, and it further prevents the corrosion of the metallic parts of the nitrification apparatus. In order to obtain this, the air, after entering the system, is passed through a series of cooling and expansion apparatus. From the intake 58 it passes into a compressor 56, worked by an engine 55, whence it passes into pipe 59, cooled by water cooler 60. A trap, 61, here allows the moisture removed thus far to drain off, while the air passes on through pipe 62 into another cooler 63, where more moisture is removed by trap 65. It next enters the expansion engine 57, where it is still further cooled; and from there passes successively into two apparatuses, 49 and 48, which serve as coolers for the nitrogen compounds coming from the nitrification apparatus, and where the cooled air acts as a cooling medium in order to condense the nitrogen tetroxide and trioxide. From receiver 48 the cold, dry air passes through pipe 66 into the distributing chamber 46, arranged at the top of chamber 45, whence it enters the nitrification apparatus 36. After nitrification, it passes out by conduit 4, depositing any nitric acid which may have been formed in trap 47, and then enters successively the coolers 48 and 49. In the first one of these it is cooled to about 0° C., in order to condense substantially all the nitrogen tetroxide, which collects in the receiving vessel 51. The second apparatus is cooled still further in order to condense all the nitrogen trioxide which collects in receiver 52. From receiver 52 the gases pass through pipe 53 into cooler 63, where they again act as cooling mediums, and are finally discharged from opening 67 by blower 70, assisting, if necessary, in the circulation. It is stated that in this process the amount of nitrous products is only about 2 to 3 per cent. of the amount of air supplied, by which means the waste due to dissociation by the action of the arcs on the combination products already formed is said to be substantially prevented. The nitrous products are obtained as such, *i. e.*, as anhydrous oxides of nitrogen. In collecting the products by the use of sulphuric acid, the gases are drawn in an upward direction through a tower filled with obstructing material, over which the sulphuric acid introduced at the top of the tower trickles down. The acid absorbs substantially all the

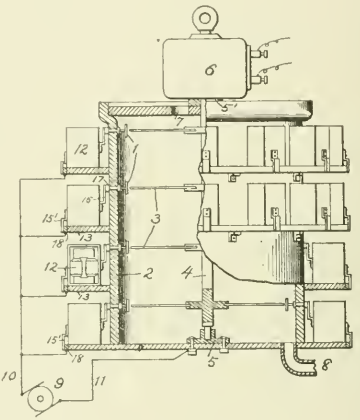

FIG. 2—FIXATION OF NITROGEN FROM THE AIR.

nitrous products, and passes then into a heated receptacle, where the expulsion of the nitrous products as vapor takes place, such vapor passing through a condensing apparatus into a suitable receptacle.

*Apparatus for Subjecting Gases to High-Tension Discharges.* Charles S. Bradley, New York, and D. R. Lovejoy, Niagara Falls, N. Y. Patent No. 709,869, September 30, 1902. Application filed March 9, 1900.

This specification describes the apparatus used in the process described above. Figs. 2 and 3 supplement Fig. 19 in Professor

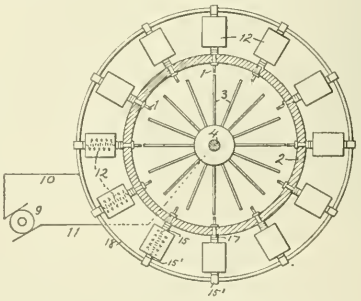

FIG. 3—FIXATION OF NITROGEN FROM THE AIR.

Richards' article, on page 21 of Vol I of this journal, and present a partly sectional elevation and a horizontal section of the apparatus. Fig. 4 represents a movable shaft, having a series of terminals 3, and connected to one pole of the dynamo 9, by means of wire 11 and bearing 5. Immediately opposite the terminals 3 are arranged opposing terminals 1, connected in parallel to the other pole of the dynamo by means of wire 10, and having included in the connection an inductance or self-induction device 12, represented as consisting of coils of wire connected in series and wound on a core of magnetic material.

To facilitate the connecting of these induction coils, they are arranged on annular shelves 13, and bear on one side by their terminal 15, against a strip 17, which is connected to terminal 1, and on the other side by their terminal 15 against a contact ring 18, connected in parallel with the other contact rings by wire 10 to dynamo 9, as noted above; 6 is the motor which revolves the shaft 4; the air enters the apparatus at opening 7, and is drawn off through opening 8. The operation of the apparatus, supplemented by a number of practical details and illustrations, is fully described by Prof. Joseph W. Richards in this journal, Vol. I, pages 11 to 23. The inventors state that the apparatus, though adapted to carry out the process of nitrification of air by exposing a current of air to the action of intermittently elongated and interrupted arcs, may also be applied to the treatment of other gases or mixtures of gases with electric discharges.

*Rotary Apparatus for the Production of Diffused Electric Discharges.* Mauris Otto, Neuilly, France. Patent No. 707,797, August 26, 1902. Application filed November 12, 1901.

This invention relates to an improved rotating machine for effecting a continuous and uniform discharge of electricity across a space through which a quantity of gas may be caused to pass in order that it may be subjected to electrical treatment. The construction of the apparatus, which is specially designed for the formation of ozone by silent discharge, is shown by Fig. 4. It consists essentially of a metallic plate *h*, which

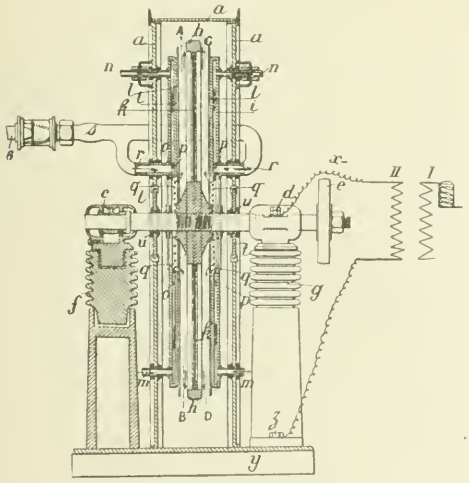

FIG. 4.—OZONIZER.

serves as one of the electrodes of the apparatus and can be rotated around an axle *b*. Opposed to it are disks *i*, one on each side of *h*, which constitute the other electrode, and are covered with an insulating film or a lining of dielectric material *l*, on the side towards the revolving plate *h*. The disks *i* are hollow, for the purpose of being cooled by cold air or refrigerated water, entering through tubes *m*, *m*, and leaving through tubes *n*, *n*. Pipe *s* supplies air to the apparatus by its two branches, which air enters the inclosed space between the movable electrode *h* and the disks *i*, and there receives the diffused discharges, which shoot across the space between the electrodes. The oxygen of the air is by this means partially transformed into ozone. I designates the primary of a transformer, at low tension, and II is the secondary, at high tension, of that transformer. The air-containing ozone is drawn off at the bottom of the apparatus.

*Ozonizing Apparatus.* Alexander Vosmaer, Haarlem, Netherlands. Patent No. 709,427, September 16, 1902. Application filed October 4, 1901.

This apparatus is also an ozonizing apparatus, of simple construction, in which the electrodes are completely independent of the casing of the apparatus in which the air circulates, and from which they can be easily removed and replaced when necessary. The arrangement consists of two electrodes placed horizontally into a tube, preferably an ordinary gas pipe. The electrodes comprise a metal bar, of any suitable metal, of square or rectangular section, in which are fixed at intervals supports of insulating material, like porcelain, having at their upper part a fork, in which rests the other electrode. The other electrode the inventor designates as the discharger, and it is provided with a number of pins or points. The current of air to be ozonized enters at one of the ends of the upper tube and passes out through the other, consequently circulating in the plane wherein the electric discharges take place. This arrangement comprises one complete unit of the apparatus, and it is obvious that the apparatus may consist of a number of similar tubes, having a common inlet and outlet. An apparatus of considerable power can thus be easily constructed by arranging the tubes in a similar manner as in the crown sheet of a boiler or a surface condenser. The easy manner in which the electrodes can be replaced constitutes one of the principal advantages of the apparatus.

## ELECTROCHEMISTRY AT THE WORLD'S FAIR, ST. LOUIS.*

By W. E. GOLDSBOROUGH.

At St. Louis there is in process of development an International Exposition in which this Society can but be deeply interested. It will be brought to completion and presented for the education of the people of our country and the world at large, just at the time when the electrochemical industries of America will be acquiring that strength which will make them a most important element in our national life. Already I have heard it said by more than one distinguished foreigner, that America is regarded as having gained an unimpeachable position and prominence in the building up of this new industry, and I cannot but think our Society hears these admissions with no small degree of pride and satisfaction.

To my mind, it is right and highly desirable that an intimate knowledge of conditions should exist between the electrochemists and the officers of the Exposition. By the officers of the Exposition I am commissioned not only to extend to you a hearty invitation to participate in their great undertaking, but to go further, and assure you that in a most helpful spirit, they extend to you assurances of their great desire to place the resources of the Exposition at your command to the end of picturing in a way that will attract international attention, the true worth and vigor of this infant industry.

In accordance with the provisions of the official classification of the Exposition, the products of the electrochemical processes will be shown in several of the exhibit buildings. Manufacturers, liberal arts, machinery, and mines and metallurgy, as well as electricity, come in for a share of these products. And, indeed, it will be proper to exhibit certain electrolytic processes in the Palace of Liberal Arts, and certain others in the Palace of Mines and Metallurgy; but to electricity, in unrestricted measure, is accorded the privilege of giving expressions to all electrochemical operations, whether purely electrolytic in character, whether brought about by electrothermic means simply, or whether attained by a combination of electrothermic and electrolytic methods.

* Abstract of a paper presented before the Niagara Falls Convention of the American Electrochemical Society, September 17, 1902.

In the Department of Electricity one of its five groups is entirely devoted to electrochemistry.

Class 434 of this group is devoted to primary batteries, and storage batteries. In this class, in addition to an exhibit of the finished products, efficiency tests of batteries will be inaugurated and a careful record kept of their performance during the period of the Exposition. In addition to these, processes in the manufacture of various types of storage batteries will, it is hoped, be arranged for, in order that this matter may be pictured in a broad way.

Class 435 embraces electrolytic appliances and processes. All forms of electroplating, methods of electrotyping, and finally and most important, the applications of electrolysis in the reduction of ores and other related work, find place here; that this class presents the possibility of a most interesting and instructive series of exhibits will be at once recognized. Electrolysis plays an even greater and more important part in the business of the world each year. It has attained to a well-recognized position. Yet, with increasing emphasis, the work we see about us here at Niagara Falls, demands for it an even broader and more important recognition.

Class 436 deals with electrothermic appliances and methods, and, therefore, includes all of the electric furnace applications which we have found pictured in the great local factories on such a large scale. Nothing is more impressive than an inspection of the actual work of the electric furnace. We are in fact almost appalled in noting the wonderful results, both in magnitude and industrial importance, which are brought about by the dissipation of electric energy by these means, and its transformation into heat. The electric arc, when applied on a large scale, attracts and rivets the attention, not only of the initiated, but the uninitiated as well. It presents the picture of power in a most fascinating way.

Class 437 deals with the application of electricity to industrial chemistry, disinfection of sewerage water, manufacture of bleaching powder, caustic soda, nitric acid, chlorate of potash, etc., etc. Much can be done to make the exhibits in this class of great value and interest, not only to students, but to engineers and chemists. Some of the most interesting electrochemical operations find expression in the field of industrial chemistry, and a strenuous effort will be made to show all of its important divisions.

With the brief outline that I have given you, you will begin to appreciate the immensity of the task which is set for those servants of the Exposition, who will bring to its full realization the hope which I entertain for the success of the electrochemical group. That all the help and assistance which you as electrochemists can offer us will be most acceptable and gratefully received, it is hardly necessary for me to say. That I ask it, is because I believe you are as deeply interested as myself in having an adequate picture of what you are doing presented to the world. In my judgment a large and fine exhibit in this group will have a most beneficial effect upon the development along electrochemical lines. If, to-day, the financiers and people of the country generally had great confidence in the ability of electrochemists to carry to a successful issue all that is rightly claimed for electrochemistry, and if "electrochemistry" had become as much of a household word among our people, as have the technical terms employed in the older and better known branches of industry, it is safe to say that the money which will be investing in and about Niagara Falls within the next few years, would from the very force of the confidence of the general public, be augmented many fold. We, at the Exposition, are not therefore attempting anything that is illogical or unreasonable, when we plan to show all of the electrochemical processes I have mentioned in actual operation, and to show as many of them as may be possible on a commercial scale.

In the Electricity Building, as you doubtless know, space will be free to exhibitors, and provision has been made to supply exhibitors with free power within reason. The installation facilities are also all that can be asked, inasmuch as the railroad lines will be extended right into the Electricity Building during the period of installation, and traveling cranes and movable hoists will be provided over all of the principal aisles in the building.

At the present time the success of the exhibits in the Electricity Department can be said to be assured, inasmuch as a large number of most interesting working exhibits have already been arranged for in the allied branches. A maximum load of 2,000 horse-power will be available for the development for the working exhibits, and without doubt the building will teem with light and activity.

Within the next two years we will have time to give the topic which has been the subject of my talk the careful attention and thought which it needs, as well as the strenuous effort and labor which its development deserves. From the interest you have been good enough to manifest in what I have said, I feel assured of your helpful co-operation and advice in this very important department of my work, and I hope I have not lead you to expect anything that will not be fully realized.

In closing, I wish to say, that the chief of the Department of Mines and Metallurgy has extended to you through me the most cordial assurances of the interest which he takes in this work. It is his desire that in all its details the applications of electricity to metallurgy shall be given the fullest expression.

## ELECTROCHEMICAL THEORIES ILLUSTRATED BY EXAMPLES FROM PRACTICE.

### FARADAY'S LAW AND THE THEORY OF ELECTRONS.

The most puzzling point to the electrical engineer when he first undertakes the study of electrochemical problems is the very important part which the valence plays in Faraday's law. As an example, the final step of the Siemens & Halske copper process consists in depositing copper from a Cu $SO_4$ solution, while the final step of the Hoepfner process consists in depositing copper from a Cu Cl solution. With the same number of ampère hours, one obtains twice as much copper from the Cu Cl solution as from the Cu $SO_4$ solution. The reason is, of course, that Cu is monovalent in Cu Cl and bivalent in Cu $SO_4$. But to someone who does not fully understand the meaning of "valence" such a statement means nothing. For a full understanding of the part which the valence plays in electrolysis, it is necessary to approach the problem from the chemical side; it is then easy to apply the chemical theory of valence to electrochemical phenomena. In this way notations and terms which appear purely formal from the chemical point of view get a very substantial meaning when applied to electrochemistry.

*Valence, Bonds.*—The notation introduced by Prof. Otis C. Johnson is particularly suitable for our purpose. While for a detailed study of his notation the reader must be referred to Prescott and Johnson's "Qualitative Chemical Analysis," we will here briefly state the fundamental points. A bond—that is, a unit of *active valence*—is either a plus one or a minus one. The oxidation of an element is shown by an increase, and its reduction by a decrease of the number of bonds. Hydrogen (in combination) has always two negative bonds. Oxygen (in combination) has always two negative bonds. Free elements have no bonds. The sum of the bonds of any compound is zero. In salts the bond of the metal is always positive. In acids and in salts the acid radical has always negative bonds. These rules enable one easily to determine the valence in any compound. For instance, in HCl, H has one positive bond, hence Cl must have one negative bond in order to have the sum of all the bonds in the molecule equal to zero. In $H_2SO_4$, $H_2$ has two positive bonds and $O_4$ eight negative bonds, hence S has six positive bonds, or the radical $SO_4$ has two negative bonds. In our example noted above we had CuCl and $CuSO_4$. In CuCl, Cl has one negative bond, hence Cu one

positive bond. In $CuSO_4$, $SO_4$ has two negative bonds, hence Cu two positive bonds. In other words, Cu is monovalent in the first case and bivalent in the second case.

Johnson has also given the following simple rule for balancing equations which represent oxidation and reduction: "The number of bonds changed in one molecule of each shows the number of molecules of the other which must be taken, the words 'each' and 'other' referring to the oxidizing and reducing agents." One example may illustrate this rule, which appears to be purely formal from a chemical point of view, while its physical meaning will be shown below. In the Bunsen cell Zn is oxidized; it becomes $ZnSO_4$. The metal Zn has no bond. Zn in $ZnSO_4$ has two positive bonds, hence the increase in bonds is two. There are several actions possible at the other electrode. We may consider that of the development of NO. N in $HNO_3$ has five positive bonds, while in NO it has two positive bonds, hence the decrease in bonds is three. Now, Johnson's rule states that we have to take three molecules of Zn and two molecules of $HNO_3$, and we get the equation

$$3\ Zn + 3\ H_2SO_4 + 2\ HNO_3 = 3\ ZnSO_4 + 2\ NO + 4\ H_2O.$$

*Faraday's Law.*—The amount of electrochemical action produced (*i. e.*, of oxidation at the anode and of reduction at the cathode) is directly proportional to the product of ampere hours and the chemical equivalent. In other words, when a certain quantity of electricity (measured in coulombs or in ampère hours) passes through a certain electrolyte, a certain definite quantity of material is reduced at the cathode and oxidized at the anode. For instance, when 96,540 coulombs pass through CuCl, we know that one gram atom Cu is deposited upon the cathode and one gram atom Cl is liberated at the anode. We may form the following mechanical scheme as an illustration of what happens in the electrolyte. We may think that the passing of an electric current from the anode to the cathode is brought about by the cations Cu charged with positive electricity and giving off their charges to the cathode, and by the anions Cl charged with negative electricity and giving off their charges to the anode. We must then assume that in this case each gram ion Cu carries with it a charge of 96,540 positive coulombs, and each Cl ion 96,540 negative coulombs. When one gram atom Cu is deposited upon the cathode, it gives off its charge of + 96,540 coulombs, and at the same time one gram atom Cl is set free at the anode and gives off its charge of — 96,540 coulombs. In other words, 96,540 coulombs are taken off from the anode and given to the cathode, with the result that 96,540 coulombs "have passed through the electrolyte."

If we have $CuSO_4$, instead of CuCl, we know from experience that when $2 \times 96{,}540$ coulombs pass one gram atom Cu is deposited upon the cathode and one gram ion $SO_4$ reacts at the anode. In this case we must assume that one gram atom Cu is charged with $2 \times 96{,}540$ positive coulombs and one gram ion $SO_4$ is charged with $2 \times 96{,}540$ negative coulombs. Cu is here bivalent, and has here twice the charge which it has in CuCl, where it is univalent. In general, *any gram ion is always charged with so many times 96,540 coulombs as it has bonds in Johnson's notation. Positive bonds represent a positive charge, negative bonds a negative charge.*

Johnson's rule of balancing equations representing oxidation and reduction becomes self evident if applied to an electrochemical action. It simply means that just as much electricity passes from the anode into the electrolyte as from the electrolyte into the cathode. In the case of equation (1), if the chemical symbols represent gram atoms or gram molecules, then, as Zn gains two bonds and as we have three Zn atoms, $3 \times 2 \times 96{,}540$ coulombs pass into the electrolyte from the anode. On the other hand, N loses three bonds, and, as two N are reduced, $2 \times 3 \times 96{,}540$ coulombs are given off to the cathode.*

* Of course, we may consider $HNO_3$ to be ionized into H and $NO_3$ ions, both univalent, etc. The result is the same as above

*Faraday's Law and the Theory of Electrons.*—We may go a step further and apply the modern theory of electrons to our problem. This has been done by Nernst. We will assume there are positive and negative electrons, although only negative electrons have so far been isolated. We may consider them as kinds of new elements (only for the sake of illustration), with so small atomic weights that, for all practical calculations, they may be considered zero; while their characteristic and distinguishing feature is that each positive electron has an electric charge of 96,540 positive coulombs, and each negative electron has an electric charge of 96,540 negative coulombs. Nernst, therefore, considers any univalent positive gram ion as a compound of the gram atom with a positive electron; also any bivalent gram ion as a compound of the gram atom with two electrons, and so on. This view emphasizes the essential difference between atoms and ions, and at the same time gives a very convenient scheme for applying Faraday's law. Johnson's bonds are, then, a very substantial thing. His positive bonds are positive electrons, and his negative bonds are negative electrons. This view, although it may be called very hypothetical, offers the safest method of applying Faraday's law. There is no possibility of making a mistake if we always keep the mechanical model in mind. Take our equation (1). As mentioned above, each Zn atom gains two bonds—that is, in our new model—while the Zn atom on the electrode has no inherent electric charge, the Zn ion in the solution (as we may consider the $ZnSO_4$ solution to be ionized into Zn ions and $SO_4$ ions) is combined with two positive electrons (because it has two bonds). Hence, if the symbols in equation (1) represent gram atoms or gram molecules, three gram atoms Zn become three bivalent ions, *i. e.*, get a charge of $6 \times 96{,}540$ coulombs. In other words, the equation (1) represents the chemical action if $6 \times 96{,}540$ coulombs pass through the system. If one only knows what the oxidation and reduction is at the two electrodes, one can calculate the whole matter. Johnson's rule for balancing equations enables one to write down the equation which represents the electrochemical action, and there is no mistake possible if one keeps in mind that each bond corresponds to 96,540 coulombs, if the chemical masses are measured in gram atoms or gram molecules.

## CURRENT NOTES.

OUR esteemed contemporary, *The Engineering and Mining Journal* announces that its chief editor, Dr. David T. Day, and its managing editor, Mr. E. W. Parker, have resigned, the former on account of the urgent demands of his work on the Geological Survey and the latter on account of the onerous work and the responsibility devolving upon him as a member of the Anthracite Coal Strike Commission. The new editor will be Mr. J. A. Rickard, with Messrs. F. Hobart, J. Struthers and S. Sanford as associate editors and Messrs. R. W. Raymond, W. R. Ingalls, J. A. Church, R. A. F. Penrose, Jr., S. F. Emmons, W. H. Weed, P. Argall, A. G. Charleton and D. J. Day as "special contributors."

THE eighty-third meeting of the American Institute of Mining Engineers was held in New Haven, Conn., from October 14th to 17th. The list of members and guests registered comprised about 60 names. (At the last Niagara meeting of the much smaller American Electrochemical Society about 160 members and guests had registered.) Some 20 papers were read, partly in title. Among the papers read was one by Dr. Leonard Waldo, on the measurement of high furnace temperatures, in which he pointed out the many important applications of the pyrometer. Visits were made to the Yale University, and especially the Peabody Museum, and a geological excursion was made to West Rock.

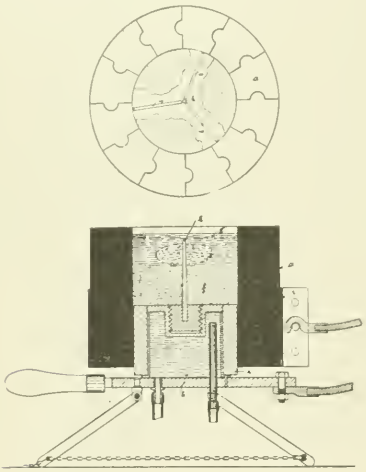
# SYNOPSIS OF ARTICLES IN OTHER JOURNALS.

*A Summary of Articles on Electrochemistry and Allied Subjects Appearing in American and Foreign Periodicals.*

By Carl Hering.

## INDUSTRIAL ELECTROCHEMISTRY.

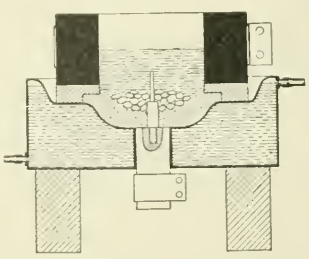
*Metallic Calcium.*—The production of calcium from its compounds by electrolysis has generally been considered to be very difficult, and it is therefore of some interest to see that Borchers and Stockem have succeeded in producing metallic calcium from some of its compounds, on such a scale that the process is claimed to be applicable on a commercial scale. The



Borchers and Stockem Calcium Furnace.

question naturally arises, what is to be done with this metal, which is not now used in that form? But, like in other similar cases, the reason why it has not been used is probably because it was not a cheap commercial article, and when it becomes so good uses for it will no doubt be found. Their process is described, with illustrations, in the *Zeit. f. Elektrochemie*, October 2, 1902. They have found that it is quite easy to deposit large quantities of calcium, by electrolysis, of electrically-fused calcium chloride, which is free from water. They use a small cathode opposite a large anode, and keep the temperature at a red heat above the melting point of calcium chloride, but below the melting point of metallic calcium; the calcium is then deposited at the cathode in a spongy form. This sponge forms such a coherent mass that it can be easily removed from the cell. If the sponge is then at once put into a suitable liquid, free from oxygen, one obtains a sponge of 50 or 60 per cent. free metallic calcium, mixed with calcium chloride. If the sponge is pressed before it is removed from the cell, it welds itself into a dense, bright mass, containing about 90 per cent. of calcium. Instead of calcium chloride, other calcium salts, especially calcium fluoride, may be used. The addition of calcium fluoride to calcium chloride has no unfavorable action; the authors prefer to use calcium chloride because it is cheap, and it has such a melting point that by exceeding it slightly one at once obtains that temperature which is best for the formation of the coherent sponge without necessitating careful temperature measurements. If the temperature is raised beyond the melting point of calcium, there are unnecessary heat losses and a tendency to re-dissolve the deposited metallic calcium, presumably by the chlorine gas. The apparatus used by the authors is shown in the adjoining diagram. The case, containing the fused salt, is the cylinder *a*, which consists of carbon rods put together like the pieces of wood of a wooden barrel, and held together by a metallic ring *r*. This forms the anode and connection to the external source of current made through the metallic ring *r*. The cylinder is closed at the bottom by a cooling apparatus *h*. The cathode consists of an iron rod *k*, placed into the cooling apparatus, the frame of the latter forming the connection with the negative pole of the source of current. The iron cylinder *a* and the cooling apparatus *h* are, of course, separated from one another by an insulating layer *i* of clay or other suitable refractory material. The lower part of the case is filled with compressed calcium fluoride *f*, the greatest part of which remains solid during the operation, on account of its higher melting point, and because it is cooled from *h*. In this way the fused chloride of calcium is protected against coming into contact with and receiving impurities from the bottom of the case. Above the fluoride there is placed the calcium chloride *c*. In order to fuse it and to start the process, several thin carbon rods *x* are provided, which short-circuit the cathode *k* with the anode carbon cylinder. When the circuit is closed, the current melts the top of the calcium chloride, after which the rods *x* are removed and the electrolytic operation is started. They mention briefly that in afterwards treating the calcium thus produced, they obtain crystals which seem to be CaCl.

*Pure Strontium.*—These same experimenters have also shown how pure strontium may be produced in a very similar way, the illustrated description being in the same number of that journal. It is a short article, in which they say that they have succeeded in using this calcium apparatus, just described, with a slight modification, for the production of pure strontium in large quantities. By electrolyzing electrically-fused strontium chloride in their calcium apparatus, they obtained metallic strontium, not in the form of sponge, but in form of fused globules, of about the same specific gravity as the bath. Much strontium was mechanically transfused to the anode, and this represents losses, causing a poor ampère-hour efficiency. The apparatus was therefore modified, as shown in the adjoining

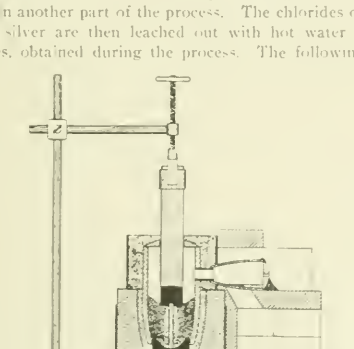


Borchers and Stockem Strontium Furnace.

diagram. The cathode, which was an iron rod, passes up from below through the cooling apparatus, but only to such a height that it is about at a level with the carbon cylinder, which forms the anode and rests upon an insulating ring, which separates it from the cooling apparatus. The bottom of the case is filled with a solid mass, with a pit in the center part, in which the strontium deposited at the cathode in form of globules remains

at rest and becomes solid, as it is cooled from below. In the lower part of the solid mass globules of pure metallic strontium are found, of diameters up to 10 mm., after the electrolysis is finished. Strontium is, like calcium, a white metal, and just as soft as lead.

*Reducing Zinc from its Ores.*—The production of zinc from its compounds involves difficulties due to the very electropositive nature of that metal, or, to put it into more modern terms, on account of the high value of the energy of combination of zinc compounds. In electrolysis this means the use of such high voltages that other undesirable reactions take place, for which that voltage is more than sufficient. In aqueous solutions, for instance, hydrogen is liberated much more easily than zinc. Such processes are therefore of special interest; all the more so as the electric methods have not yet come into use as much as might be expected. In a recent article in the *Zeit f Elektrochemie*, September 25, 1902, DANNEEL describes several zinc processes which were worked out at the metallurgical laboratory of the Institute of Technology of Aix-la-Chapelle, Germany. The first one is devised by Borchers, the director of the laboratory, and Dorsemagen. They chlorinate raw ore in the presence of salt solutions, such as sodium chloride and magnesium chloride, in revolving iron drums, lined with lead, at a temperature of 30° to 40° C., by means of free chlorine, obtained in another part of the process. The chlorides of lead, zinc and silver are then leached out with hot water or hot dilute lyes, obtained during the process. The following data



DORSEMAGEN FURNACE FOR THE PRODUCTION OF ZINC AND SILICON CARBIDE.

of a test are given: 1,000 kg. ore contained 140 kg. lead, 310 kg. zinc, 0.69 kg. silver. There were chlorinated and leached out 140 kg. lead, 175 kg. zinc, 0.11 kg. silver. In the residue there remained 135 kg. zinc, 0.53 kg. silver and 115 kg. sulphur. After the extraction of the sulphur, there remained a residue of 39.1 per cent. zinc and 0.168 per cent. silver. From the residue, the sulphur is removed by Schaffner's method under steam pressure. The chloride lyes are purified by means of zinc oxide or roasted zinc ore, evaporated to dryness and dehydrated as completely as possible. The dehydrated mixture of chlorides is then electrolyzed in a fused state, and at the anode the chlorine gas is obtained which is used in another step of the process, as mentioned above; while at the cathode a mixture of molten lead and zinc is produced, which is obtained in two alloys—lead poor in zinc and zinc poor in lead. From the lead which is poor in zinc, the zinc can be removed by steam; the zinc which is poor in lead is refined by distillation. A large experimental plant for studying this process on an industrial scale is being installed by F. Krupp.

The second process described was devised by Borchers and von Kuegelgen, and is for treating the waste from zinc galvanizers. This waste is dissolved in hydrochloric acid to saturation. The iron is removed from the solution by means of chloride of lime and other oxidizing agents; it is then evaporated to dryness in iron crucibles lined with lead. The pulverized zinc chloride is mixed with metallic oxides—for instance, copper oxide and calcium carbide—and is then melted to zinc alloys—for instance, brass. The reaction between zinc chloride, metallic oxide and calcium carbide goes on by itself, flowing to its own heat of reaction, after the reaction has been started by means of an incandescent body; but to obtain good metal it is necessary to heat the crucible.

The third process described was devised by Dorsemagen, for the treatment of siliceous zinc ore, especially if the percentage of zinc is small; zinc and silicon carbide (carborundum) are produced. An electric furnace is used, as shown in the adjoining diagram. A mixture of carbon and siliceous zinc ore is heated in the furnace by a carbon rod; the zinc is distilled off, and there remains silicon carbide. The reduction temperature of the silica is only slightly above the distillation temperature of zinc.

The fourth process described is by Borchers and Dorsemagen, and is quite analogous to the last one described. It is used for the treatment of ores containing iron and zinc, in order to get ferrosilicon and iron. The process differs from the last one only in so far as ferrosilicon, instead of silicon carbide, is obtained.

*Lead Refining.*—Lead is being refined from its bullion by the Betts process, in a plant having a capacity of about 10 tons daily. It is said to have a low working cost and a high efficiency. This plant is described by ULKE in the *Engineering and Mining Journal*, October 11, 1902. The general arrangement of the plant is very similar to that of a copper refinery. The success of the process is based upon the solubility of lead in an acid solution of lead fluosilicate, which has both stability under electrolysis and high conductivity, and from which very pure lead is said to be deposited with impure anodes at a very low cost. The solution is obtained by diluting hydrofluoric acid of 35 per cent. H. F. with an equal volume of water and saturating it with pulverized quartz. The anodes consist of the lead bullion to be refined, cast into plates about 2 inches thick. The cathode sheets, which receive the regular lead deposits, are thin lead plates, obtained by electrodeposition upon and stripping from special cathodes of sheet steel. The anodes and cathodes are separated by a space of 1.5 to 2 inches in the tank; the tanks are in series; the fall in potential between tanks is only 0.2 volt. Current densities of from 10 to 25 amperes per square foot have been used, but 14 amperes have given the most satisfactory results. According to the inventor, "260,000 ampere hours at 0.25 volt works out to 87 electric horse-power hours, or 100 horse-power hours at the engine shaft, in round numbers. Estimating that 1 horse power hour requires the burning of 1.5 pounds of coal, and allowing, say, 60 pounds for casting the anodes and refined lead, each ton of lead refined requires the burning of 210 pounds of fuel." Practically all the impurities in the base bullion remain as a more or less adherent coating on the anode, and only the zinc, iron, cobalt and nickel practically go into solution. The anode residue consists practically of all the copper, antimony, bismuth, arsenic, silver and gold contained in the bullion, and very nearly 10 per cent of its weight in lead. The silver slimes obtained, averaging about 8,000 ounces of gold and silver per ton, are now treated at the Seattle Smelting and Refining Works.

*Copper Depositing.*—A description of the Dessolle process of copper plating, in which the electrolyte is projected under pressure against the metallic object and the anodes, is published in a recent number of the *Journ. Soc. Chem. Ind.*, an abstract of which may be found in the *Lond. Elec.*, October 3, 1902. The metallic objects are first cleansed, either in an acid bath or by means of a jet of sand driven by compressed air, which rapidly removes all impurities. They are next placed in a preparatory bath and subjected to the action of a current of 30 amperes per square meter. The composition of this so-

called "adhesion bath" is as follows: Double cyanide of potassium and copper, 4 parts; potassium cyanide, 0.5 part; ammonia, 0.5 part; water, 94 parts. On leaving this bath, the objects are carefully examined, and any trifling holes in the deposit stopped with solder, or, if larger, with spongy tin, obtained by electrolysis. They are next immersed in the principal bath, which has the following composition: Crystalline copper sulphate, 12; free sulphuric acid (65 degrees), 3; water, 85 parts. Jets of this liquid are driven against the surface and that of the anodes. This effects a removal of gas and impurities from the bath and enables a strong current to be used, so that a perfectly smooth deposit of copper is obtained. In Dessolle's installation a current with an ampèrage of 750 is employed, and a deposit of 1-10 mm. is obtained in one and one-half hours, a rapidity of deposit which is stated to have no prejudicial effect upon the quality. The temperature is maintained at the required degree by means of steam jets, viz.: at 50° C. in the adhesion bath and at 35° C. in the final bath. The electrolyte projected by the jets falls into a central tank below, whence it is raised by means of wooden pumps to a reservoir fixed at a height of 5 meters above the level of the bath, and falls through the jets again under considerable pressure. Finally, the plated articles are dried and polished in the usual way. The price of plating metals with a good deposit of copper does not exceed 2 fr. per kilogramme of deposit, but the economic advantage of the Dessolle process is that there is perfect adhesion of the deposit, which can be made thicker and yet be durable.

There is another, but very short, article on the use of copper deposits to hold together pieces of glass, by forming a sort of beading on the edges of copper strips placed between the edges of the pieces of glass or prisms, by which means composite structures, like reflectors or refractors, are built up. The method seems to be used in place of the usual burned lead strips in colored-glass windows. It is very briefly described in the *Lond. Elec. Rev.*, October 10, 1902.

*Manufacture of Aluminum.*—A Bunsen Society paper, in which Haber describes a series of experiments to show on a small scale the principal points which are of importance for the success of the manufacture on a large scale, is given in the *Zeit. f. Elektrochemie*, August 21, 1902.

*Graphite.*—The change of amorphous carbon into graphite was known to have occurred at the high temperature of the arc, but it was not until Acheson discovered the necessary intermediate action that it became possible to succeed in doing this commercially. He showed that to bring about the change it was necessary to first form some compound of carbon and then dissociate this, setting free the other element. The carbon which remains will then be in the form of graphite. Danneel, in the *Zeit. f. Elektrochemie*, September 25, 1902, gives an account of an investigation of this transformation by Borchers and Moegenburg. They found, as Acheson did, that this conversion is very difficult when absolutely pure carbon is used, but it is greatly accelerated if metals or metallic compounds are present which are able to form more or less dissociable carbides. During dissociation the metal is evaporated, and the carbon remains as graphite. They have studied the use of iron, manganese and aluminum for this purpose, and have found that iron is least suitable, while aluminum is the most convenient and effective material. Although the reduction temperature of aluminum oxide is somewhat above that of manganese oxides, yet aluminum is more volatile than manganese. The quantities of aluminum or aluminum oxide required are relatively small. Aluminum is even considerably more effective than boric acid, phosphoric acid, etc.

*Chlorates.*—J. B. C. Kershaw's second article on electrolytic manufacture of chlorates is published in the *Elec Rev.*, October 11, 1902. In this part he discusses the Corbin cell and the Franchot and Gibbs cell, and makes some remarks on the efficiency of the various processes. He gives an estimate of the cost of chlorate of potash, made in a 3,000 horse-power hydroelectric plant, producing 1,600 metric tons of chlorate. The cost per pound of chlorate is 4.7 cents. He then gives a summary of numerous laboratory investigations bearing on the theory of chlorate cell. Foerster, Mueller and Jorre state that the reduction of the cathode can be suppressed either by use of calcium chloride or of potassium chloride. The electrolyte should be slightly acidified to liberate hypochlorous acid. A large volume of electrolyte should be used, and should be kept in vigorous agitation, in order to allow the secondary reactions to occur as rapidly as possible. The temperature of the electrolyte should be maintained above 40° C. to promote circulation, to reduce the e. m. f. and to diminish the formation of perchlorates, which otherwise would occur. Tucker and Moody electrolyzed calcium chloride solutions, and recommended that the solution should be one of 20 per cent.; the electrodes should be of platinum, horizontal, and 10 cm. apart; the current density should be 8 ampères per square decimeter at the anode; the temperature should be maintained at 80° C.; sodium chromate or sodium hydrate should be added to the electrolyte. Foerster and Mueller state that the best efficiency is obtained when an electrolyte is used containing sodium chromate and free hydrochloric acid, in conjunction with a spongy platinum electrode. Under these conditions, two-thirds of the chloride present in the cell can be converted into chlorate, with a current efficiency averaging over 94 per cent.

*Calcium Carbide Patents.*—It is certainly a tribute to electrochemistry when an article which was almost unknown only a few years ago is now manufactured in Europe in such large quantities that it becomes necessary to force a market for it in some other country by annulling the patent in that country, yet, according to a report in the *Lond. Elec. Rev.*, October 10, 1902, this is what the United Carbide Factories of Nuremberg, Germany which is presumably the carbide trust of Germany, have decided to try to do with the Willson patents here in the United States. The European and American patents are discussed at some length.

*Alizarine Industry.*—Alizarine was formerly obtained from the root *Rubia Tinctorum*, but, since Grabe and Liebermann discovered that alizarine is a derivative of anthracene, it has been manufactured from coal tar by treating anthracene with sodium bicarbonate and sulphuric acid. This gives anthraquinone, and, according to the modern process, this is treated with fuming sulphuric acid, and the monosulphite is found with caustic soda. To obtain anthraquinone from anthracene, sodium bicarbonate is necessary. Up to the present the methods for recovering the chromium salt contained in the mother liquor as chromium sulphate have been very troublesome. The electrolytic recovery has hitherto been hindered by the fact that a diaphragm is necessary between the two electrodes, and that none was found capable of withstanding the strongly acid solution for any length of time. This difficulty is said by Simon, in the *Jahresber. Phys. Ver.*, Frankfort, 1902, to have been overcome by Leblanc's invention of diaphragms, consisting of 25 per cent. alumina and 75 per cent. silica, which not only are very durable, but also have a low resistance. One German aniline dye factory has been transferred to the neighborhood of Augsburg, where sufficient water-power is available to yield a cheap supply of electrical energy for the new process. An abstract of the article may be seen in the *Lond. Elec.*, October 3, 1902.

## THEORETICAL AND EXPERIMENTAL.

*Electrolysis of Fused Sodium Hydroxide.*—Although NaOH is usually an end product of electrolysis, and not a raw material for electrolytic conversion, yet it is of interest to know what will occur when it is electrolyzed. In the *Zeit. f. Elektrochemie*, September 11 and 18, 1902, Le Blanc and Brode give a long account of an experimental investigation of this, the principal results of which may be summed up as follows: Fused sodium hydroxide containing water has two distinct values of decomposition voltage, 1.3 and 2.2 volts. In baths which are free from water, the lower decomposition

voltage disappears. By quantitive measurements of the gases developed during electrolysis at different voltages, they found that both values of the decomposition voltage have a real meaning. At 1.3 volts there is a development of hydrogen and oxygen, while at 2.2 volts sodium and oxygen are set free. The ampère hour efficiency of the oxygen increases with increasing current density. Below 2.2 volts the efficiency of the development of hydrogen is 100 per cent. as long as no free sodium is present. In a bath free from water, and with a voltage above 2.2 volts, the cathode deposition is only sodium. It is certain that pure fused sodium hydroxide contains no H or O ions, but only Na and O H ions, the latter producing water and oxygen by secondary reaction. The phenomena of the electrolytic production of sodium by the Castner process on a large scale are also discussed

*Electrolysis of Alkaline Chlorides.*—Foerster and Mueller give a long account of a series of experiments in the *Zeit f. Elektrochemie*, August 28 and September 4, 1902, the main results of which are as follows: If equimolecular solutions of alkali hydrate, hypochlorite and chloride are electrolyzed with increasing voltage, the passage of a certain current takes place through the hydrate solution at the lowest anode potential and through the chloride solution at the highest anode potential. At an intermediary anode voltage, characteristic for the electrolysis of hypochlorite, a discharge of univalent negative Cl ions take place. At the moment of the anodic discharge univalent negation Cl ions react with water and form chlor e acid, hydrochloric acid and a development of oxygen at the anode. The anodic formation of chlorate takes place as well with solutions containing free hypochloric acid as with neutral or alkaline solutions of hypochlorites. A secondary formation of chlorate takes place in the electrolysis of the hypochlorite if the electrolyte has become somewhat rich in free hypochlor ons acid.

*Electrolytic Reduction of Nitric Acid.*—An investigation of the alterations which nitric acid will undergo by electrolysis in the neighborhood of the cathode, when considerable amounts of sulphuric or hydrochloric acid are present, is described by Tafel in the *Zeit. f. Anorgan. Chemie*, 31, 3, p. 289, 1902, an abstract of which is given in *Science Abstracts* for September, 1902. He found that a reduction will occur with most cathodes, excepting, for instance, platinum. The mean products of this process are ammonia and hydroxylamine, their ratio depending on a whole series of factors and varying to a high degree, according to the nature of the cathode, whereas the sulphuric and hydrochloric acids do not seem to exhibit any marked differences. The largest amounts of hydroxylamine are evolved with pure mercury cathodes or well-amalgamated electrodes, the formation of ammonia being almost wholly prevented in some cases, so as to obtain a nearly perfect quantitative transformation of nitric acid into hydroxylamine salt; whereas in the case of lead cathodes the amount of the acid transformed into hydroxylamine was not higher than 40 per cent.; for copper, 15 per cent. at the most. The rate of this reduction is smallest in the case of copper electrodes. It is next shown that, with electrodes giving rise to this reduction process, hydroxylamine sulphate will equally be reduced, and *vice versa*.

*Ozone.*—The electromotive behavior of ozone has been studied experimentally by Inglis, an account of which is given by Luther in a recent Bunsen Society paper, published in the *Zeit. f. Elektrochemie*, August 28, 1902. In this description Luther gives nine results obtained with an ozone electrode; that is, an electrode of platinized platinum in a solution of ozone. He found that such an electrode assumes a higher oxidation potential when the electrode was previously charged with hydrogen, and a lower one if thus saturated with oxygen. He also shows an experiment which at first sight seems very strange, as there is reduction at both electrodes, and this is contrary to one of the first principles of electrolysis, namely, that there is always oxidation (or, better, "perduction") of the electrode or the solution, or both, at the anode and reduction at the cathode. The reduction at the anode in this exceptional case is explained as a secondary action, due to a primary oxidation with a formation of a higher oxide, which is, at the same time, a more energetic reducing agent. This explanation seems quite a reasonable one.

*Electric Double Layer and Absolute Potential.*—As we cannot connect a measuring instrument, which is usually of metal, with an electrolyte without using two electrodes, it follows that all measurements of electrolytic potentials give only the algebraic sum of the two potentials at the two electrodes. It seems very difficult to find some way of measuring each separately, although several more or less doubtful methods have been suggested. It is evident that the algebraic sum of two quantities can never define the two quantities themselves, as they may both be very large or very small and yet have the same algebraic sum. Sometimes the so-called hydrogen electrode is taken as zero, from which the potential difference of any other individual electrode with an electrolyte can be determined, but this is, of course, an arbitrary scale and not an absolute one. Billitzer has attacked the problem in a different way. As described in his recent Bunsen Society paper, published in the *Zeit. f. Elektrochemie*, August 28, 1902, he endeavors to find the conditions under which the potential difference between an electrode and an electrolyte is zero. It is based upon Helmholtz's theory of the relation between potential difference and electric "double layer," or, in German, "Doppelschicht." In the discussion which followed, it was pointed out that Helmholtz, starting from the same foundation, devised another method, and that Ostwald's and Billitzer's methods, although based upon the same grounds, give very different results. The whole matter is therefore, unfortunately, still entirely in the dark. Haber called attention to another method, which had been proposed by the late Luggin Nernst proposed to consider the whole matter as hypothetical, and to use a convenient, although arbitrary, zero point by assuming the potential difference at the hydrogen electrode equal to zero.

*Free Ions.*—An account of an experimental investigation into the existence of free ions in aqueous solutions of electrolytes is given by Olsen. After some critical remarks on an older experiment by Ostwald and Nernst, he describes some experiments which he has made, and which are based on the following considerations: It is believed that an electrostatic charge attracts and repels the unlike and like charged ions respectively; and as it is the ions which, in giving up their charge, produce a current, then, if these ions can be guided by an electrostatic charge, we should get a current with electrodes indifferent to the solution, and be able to detect it with a sufficiently delicate galvanometer. The results of the experiments are given as follows: When a cell containing an electrolyte is connected to a Danneel element, although the e. m. f. is below the decomposition value of the electrolyte, the solution in the neighborhood of the anode becomes positive, or, in the neighborhood of the cathode, becomes negative, or both. After an electrolyte has been electrolyzed by a current, it is affected by an electrostatic charge in such a way that the liquid nearest the charge becomes of the opposite sign, or the liquid farthest from the charge becomes of the same sign as the charge, or both, *i. e.*, an electrolyte, after having been electrolyzed, acts as if it contained particles charged with electricity, which are free to move and may be directed by an electrostatic charge. An electrolyte subjected to an e. m. f. less than the decomposition value of the solution behaves in a similar way. Finally, an electrolyte which has never been acted upon by a current also behaves in a similar way when acted upon by an electrostatic charge, *i. e.*, it behaves as if it contained particles charged with electricity, which are free to move, and these particles have not been produced by a current. This corresponds to the definition of free ions. The paper is published in the *Am. Jour. Sc.*, October.

## MISCELLANEOUS.

Among the other recent articles may be mentioned one by [illegible] on the application of electrochemical methods to the determination of the structural formulas of silver salts, in the *Zeit. f. Elektrochemie*, September 4, 1902; a Bunsen Society paper by Zsigmondy, on colloidal solutions, chiefly on the order of magnitude of the dimensions of the particles, and especially of gold, in the same number. An illustrated description by Jorris of a mercury bath for lecture-room purposes, for showing the vapor tensions of solvents and solutions by means of a series of barometer tubes, which is also in the same number of that journal.

## PRIMARY AND SECONDARY BATTERIES.

*The Prospects for a Light Storage Battery.*—In the opinion of Norden, the lead accumulator has been so much improved in recent years that there is not much room for further progress, and the "light accumulator of the future" must be a non-lead accumulator. In his article, which is published in the *Centralblatt f. Accum.*, August 15, 1902, he first discusses former trials with metals different from lead. The zinc lead peroxide cell has a higher ampère hour capacity per pound of weight, and its discharge voltage is higher than 25 per cent. But the disadvantage is that during discharge the zinc goes into solution, and during charge it is not so perfectly and cleanly redeposited, but sometimes in spongy form, which may cause short circuits, and it is therefore impossible to avoid irregularities entirely. Moreover, local action at the zinc plate cannot be entirely avoided, in spite of amalgamation. What is said here about the zinc electrode is generally valid for any soluble electrode, as in practice there will always be trouble in redepositing the metal. He therefore claims as a general principle that a soluble electrode is unsuitable for a storage battery. He then discusses the cuprous oxide zinc accumulator, in which there is again the same trouble with the zinc. The copper plate also has disadvantages; it ought to be insoluble in the electrolyte, but at the end of the charge cupric, instead of cuprous, oxide is often formed. And as soon as a trace of cupric oxide goes into the solution, copper becomes an ion, and is deposited on the zinc, causing a fatal local action at the zinc plate, as it there forms a short-circuited copper-zinc couple. It has often been concluded that the use of two different metals is therefore impracticable in an accumulator, but this conclusion would be wrong, for if both metals are absolutely insoluble there would be no danger whatever. Moreover, the last-discussed disadvantage occurs only when the metal which is dissolved can be deposited upon the opposite pole. This is, for instance, not the case with the zinc, as it never can be deposited upon the opposite plate. He therefore claims, as a second principle, that two different metals in an accumulator are practical only when they are either both insoluble in the electrolyte or when, if dissolved, they cannot be re-deposited on the opposite plates. He then discusses the Edison accumulator, which he considers to be a step in the right direction, although he does not think that it represents the definite solution of the problem of the light accumulator. The mechanical construction, with the active material compressed in perforated boxes, is not thought to be the best construction for utilizing the total active mass, as the passage of the current into the interior of the boxes and the diffusion of the electrolyte into the pores is somewhat difficult. He thinks that the capacity of the Edison cell per pound of weight is too nearly of the order of magnitude of that of the lead cell. A new principle has not been found in the invention of the Edison accumulator, but its general importance is that it shows that with an old method, which has already been considered as being without prospects, some success can be obtained. He finally points out the impossibility of predicting anything concerning the probable future development from a purely theoretical point of view.

*Tribelhorn Storage Battery.*—It is an old device to make up a series of batteries by making the cells in the form of metallic dishes piled one over the other, with insulating separators, so that the lower surface of the upper dish is one electrode and the upper surface of the lower dish is the other electrode, the liquid being filled into the dishes. This idea, although ingenious, seems to have survived only in the Tribelhorn accumulator, made in Switzerland, and said to be used in factories, hotels and central stations. Its characteristic feature is the arrangement of the cells, which are in the form of leaden conical dishes, one above the other (quite similar to Salom's arrangement for lead reduction, recently described in these columns). The upper side of each dish is positive, the lower negative. The novel device is that the active material is keyed in peculiarly-formed furrows on both sides of the dishes. The charging voltage increases to 2.75, and the discharge voltage decreases to 1.85 at slow discharge and to 1.72 at fast discharge. The ampère-hour efficiency averages 90 to 92 per cent., and the watt-hour efficiency 68 to 70 per cent. The description, with illustrations, may be found in the *Elek. Neu. Anz.* for October 1, 1902.

*Accumulators.*—The *Centralblatt f. Accum.*, September 1, 15 and October 1, 1902, contains continuations of the descriptions of the accumulator exhibits at the Dusseldorf Exposition by the following German firms: E. Schulz, of Witten; the Pollack Accumulator Works, of Frankfort; also an exhibit by the "Accumulatoren Fabrik A. G. Hagen," on sanitary arrangement in storage-battery factories.

*E. M. F. of Ozone Cells.*—An account of an investigation of the question whether the heat produced by the decomposition of ozone—which, according to Berthelot, is 29,600 gram calories per 48 grams of ozone—can be utilized wholly or in part for the production of electrical energy is given by Brand in the *Ann. d. Phys.* No. 10, 1902, abstracted in *Lond. Elec.*, October 10, 1902. A Grove gas battery can be constructed with oxygen and ozone as elements, the current passing from the oxygen electrode through the electrolyte to the ozone electrode. To determine how much of the energy is thus transformed, it was necessary to find the e. m. f. of the cell. But, since the e. m. f. of an oxygen cell is not constant, the e. m. f. of the oxygen electrode and of the ozone electrode were determined separately by comparison with a normal mercury electrode, consisting of mercury covered with mercurous sulphate and immersed in normal sulphuric acid. Eventually the author obtained an amount of energy equal to 0.5 joule per coulomb. The total work of ozonization amounts to 0.642 joule per coulomb, so that there is a rather high electrical efficiency.

*Standard Cells.*—A German Bunsen Society paper, by Cohen, on the changes of the cadmium amalgam in Weston cells under certain conditions, and on the electromotive behavior of cadmium amalgams, is given in the *Zeit. f. Elektrochemie*, August 28, 1902.

## GENERAL AND MISCELLANEOUS.

*Magnetic Concentration.*—Hassreidter gives a description of the Mechernich system of magnetic concentration in the *Jour. Soc. Chem. Ind.*, September 30, 1902, an abstract of which will be found in the *Eng. and Min. Jour.*, November 1, 1902. The ore is delivered by an adjustable chute between two magnetic poles, the upper one of which (the north pole) is rotated. As the ore arrives in the magnetic field, the permeable particles are attracted by the north pole, and are carried around by it into zones of progressively diminishing intensity, until the centrifugal force imparted to the particles overcomes the magnetic attraction and they fall into collecting chutes, being classified according to their magnetic properties. The non-magnetic material falls directly into a chute close against the lower pole. This arrangement is claimed to have the advantages of dispensing with belt carriers, which weaken the magnetic field; and also of permitting the use of small magnetic fields and very narrow air spaces, thus minimizing the loss of energy and making it possible to attract feebly magnetic

particles by a very weak current. The rotating pole being the only moving part of the machine, the wear and tear is very small. In separating blende and siderite from the Upper Harz, the grains being of 0.5 mm. size, 98.7 per cent. of the zinc has been recovered. With dolomitic Silesian blende of 2 to 3 mm. size, the recovery was 91.8 per cent., which was increased to 93.5 per cent. by reducing the grains to 2 mm. In treating ore from Broken Hill, a yield of 81 per cent. of the lead and 60 per cent. of the zinc was obtained. A plant of this type installed at Broken Hill for the treating of middlings, assaying 28 per cent. zinc, 10 per cent. lead and 9 ounces silver per ton, furnishes a product with 44 to 45 per cent. zinc and 4.5 per cent. lead.

*Electrochemistry at the Dusseldorf Exhibition.*—DANNEEL, in the *Zeit. f. Elektrochemie*, September 25, 1902, begins a long illustrated descriptive article, in the introduction of which he describes the geology, minerals, coal mining, ores and mining installations in general in the few western provinces of Germany from which most of the exhibitors come. He then discusses the exhibits of the Aix-la-Chapelle Institute of Technology, and describes several metallurgical processes which have been worked out in its metallurgical laboratory. Abstracts of these descriptions will be found in other paragraphs of this synopsis.

*Analysis of Foodstuffs.*—An article by MEDICUS, giving an account of experiments made by Mebold on the electrolytic determination of traces of metals in foodstuffs, is given in the *Zeit. f. Elektrochemie*, September 4, 1902.

## SOME EUROPEAN ELECTROLYTIC POWER PLANTS.

By FRANK C. PERKINS.

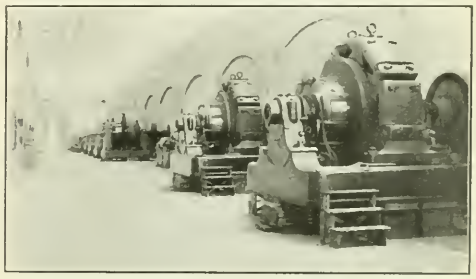
The water-powers of Switzerland which have been developed have been very extensively used for electrolytic work. The Swiss electrical manufacturers, as Brown, Boveri & Co., of Baden, and the Compagnie de L'Industrie Electrique, of Geneva, as well as the firm of Ganz & Tarsa, of Buda-Pesth, Austria-Hungary, have designed many special machines for electrolytic purposes. Among the important power plants using Swiss apparatus for the production of chlorate of potash may be mentioned those at St. Michel, Vallorbes and Cheddes, and for soda and chlorine the Usine de Gavet-Clavaux and the Usine de Monthey, Switzerland.

The Usine de Cheddes supplies the necessary power for the electrochemical production of chlorate of potash, and is located in the valley of Chamonix, the water-power being obtained from the river l'Arve, near Mont Blanc. The power house contains four Thury 8-pole direct-current generators, which operate at a speed of 240 revolutions per minute, and supply a current of 800 ampères at a potential of 700 volts. These machines were constructed by the Compagnie de l'Industrie Electrique, of Geneva, and each has a capacity of 560 kilowatts. The turbines which are directly coupled to the dynamos have a total capacity of 3,200 horse-power, or 800 horse-power each, and were built by Brenier-Neyret, of Grenoble.

The Usine de St. Michel also supplies power for the manufacture of chlorate of potash, and is located so as to take advantage of the water-power from the river l'Arc. The water conductors are 1.2 meters in diameter, and carry from 5 to 6 cubic meters, the head being about 90 meters. In this power house of St. Michel there are 12 Thury 6-pole continuous current generators, each driven by a 160 horse-power turbine of the Brenier-Neyret type. These dynamos supply a current of 500 amperes at a potential of 200 volts. There are also four 12-pole Thury direct-current machines, each supplying 1,500 ampères at a pressure of 200 volts. These machines are driven by four 450 horse-power turbines, built by A. & H. Bouvier, of Grenoble.

This same form of Thury 12-pole direct-current machine has also been employed at the Usine de la Praz for the reduction of aluminum. These machines supply 3,000 ampères at 110 volts, and operate at a speed of 250 revolutions per minute. This plant at La Praz utilizes a total of 8,600 horse-power, and is operated by the Société Electro-metallurgique Française. There are two machines at this plant, each of which supply 7,500 ampères at a potential of 35 volts, the speed being 300 revolutions per minute.

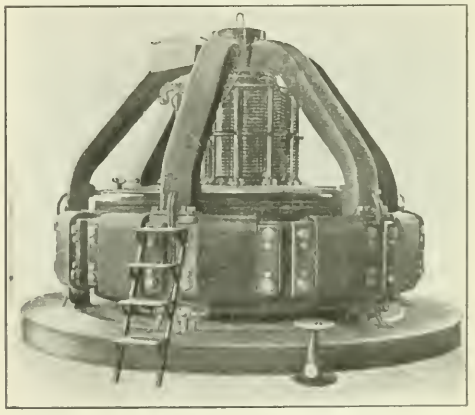
The Usine de Gavet-Clavaux is located in the valley of Bourg-d'Disan, near Grenoble, and supplies current for the production of soda and chlorine. There are two Thury 12-pole



POWER PLANT AT CHEDDES.

generators in this plant, each furnishing a current of 5,000 ampères at 75 volts, or 150 volts pressure. They are driven by four turbines of the Brenier-Neyret type. The products of the electrochemical plant at Monthey, Suisse, are noted for their purity. The sub-station at Monthey is equipped with two motor generators, the motors of which are three-phase machines, operated by a 5,000-volt current, which is transmitted a distance of 8 kilometers from the power station at Bex, Suisse, which is equipped with four 400-kilowatt three-phase machines. These two synchronous motors each have a capacity of 350 horse-power, and drive 6-pole Thury continuous-current machines, which supply 2,000 ampères at 120 volts pressure for the electrolytic work.

The electrolytic generators mentioned above have all been of the horizontal direct-current type, and before taking up the



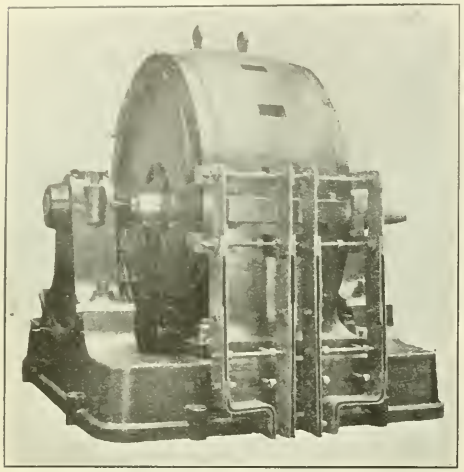
VERTICAL GENERATOR AT CHEVRES-GENEVE.

alternating current machines for the operation of electric furnaces it may be of interest to consider some of the vertical continuous-current machines used for electrochemical work.

At the Usine de la Volta, at Chèvres-Genève, Suisse, there is in operation a 12-pole Thury vertical generator, which is directly coupled to a 1,200 horse-power turbine, built by Escher,

Wyss & Co. This machine, noted in the accompanying figure, is driven at a speed of 120 revolutions per minute, and supplies a current of 4,000 ampères at a potential of 208 volts. The moving part of this machine weighs 27,500 kilograms, the total weight of the machine being about 60 tons.

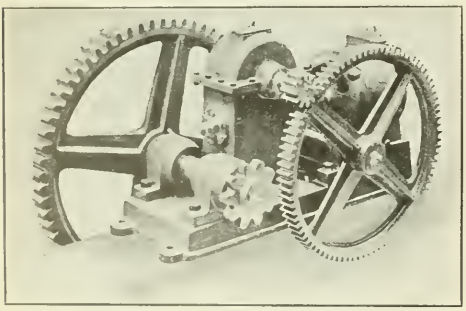
The vertical machine at Harpsborg, built by the Compagnie de l'Industrie Electrique, operates at a speed of 180 revolutions



1,500 HORSE-POWER THURY "CARBURE" ALTERNATOR.

per minute, giving 5,000 ampères at 112 volts. This machine is operated by a 750 horse-power vertical turbine.

The Thury "Carbure" alternator was designed especially for use with electric furnaces for the production of carbide of calcium. The accompanying illustration shows one of these machines of 1,500 horse-power, designed to be operated at a speed of 500 revolutions per minute. It is of the inductor type, there being no windings upon the rotating portion, and the heavy conductors bolted together may be noted in the illustration. This is a single-phase machine, and weighs 32,300



ELECTRICALLY-OPERATED WINDLASS.

pounds. It is 2,720 mm. long, 2,900 mm. high and 2,720 mm. wide. Thury has supplied a 1 horse-power three-phase motor, of 47½ cycles, for an electric windlass to regulate the carbons of the furnaces for the production of calcium carbide. This motor operates at a speed of 1,350 revolutions per minute on a 110-volt circuit, and drives the windlass or carbon regulator by means of the gearing shown in the accompanying illustration. The Société Electrochimique de la Romanche, near Grenoble, have their plant equipped with five of the Thury alternators, each of which has a capacity of 1,200 horse-power and operates at a speed of 350 revolutions per minute.

In Italy the Société Italienne pour la Fabrication du Carbure de Calcium, of Rome, have a very large power plant, using Thury alternators for the production of calcium carbide. The total capacity of this plant is 4,580 horse-power.

Ganz & Co., of Buda-Pesth, installed a number of inductor alternators at the plant at Bozen-Meran, and the current from these machines is used extensively in the works for the production of carbide of calcium. This plant is equipped with six turbines, of 1,200 horse-power each, directly coupled to 1,000-kilowatt three-phase alternators. One of the machines supplies a current of 12,000 volts pressure for long-distance transmission, and two of the alternators supply a three-phase current of 3,600 volts pressure, while the remaining two machines generate currents at both 12,000 volts and 3,600 volts potential. For use in the carbide plant, step-down transformers reduce the potential to that required.

## CORRESPONDENCE.

### MR. COWLES' PIONEER WORK.

*To the Editor of the Electrochemical Industry.*

Sir:—I have read the biographical sketch of the life of Alfred H. Cowles in the Electrochemical Industry for October, 1902. I have been and am now counsel for the Electric Smelting and Aluminum Co. in their patent litigation in relation to the manufacture of carborundum. I note in the biographical sketch the reference to the carborundum business is left as though there were doubts as to the carborundum being manufactured in accordance with the process discovered by the Cowles brothers. In justice to Mr. Cowles, I send you a copy of the opinion of the United States Appellate Court, which sat in your city some time over a year ago and passed upon the questions here involved. This decision was the final decision of the highest court. On page 11 of the opinion which I send you, you will note that it was found that the court had "no doubt on the evidence that carborundum can be, and has been, produced under the process covered by any one of the claims of the process patent in suit" (No. 319,795). "So long ago as 1884 the Messrs. Cowles produced it under their process, with and without the use of prepared or preformed central core of resistance material." Samples of carborundum were left by the Messrs. Cowles at the museum of the Institute of Technology in Boston at these early times, and during the course of this case the samples were produced and proven as having been made by the Messrs. Cowles years before Mr. Acheson began to experiment with the Cowles furnaces.

I note the word "said" is used in the same questionable manner in relation to the Cowles' work having opened up the development of calcium carbide. If you care to take the trouble to communicate with Mr. Edward N. Dickinson, Washington Life Building, New York City, the attorney for the Electric Gas Co. and Union Carbide Co., you will be able to learn that these two companies recognized the priority of the Cowles brothers in this field and are licensees under the Cowles patents, though it is a fact that Mr. Edward M. Dickinson was also the attorney for Mr. Thomas S. Willson.

Francis C. McMillin,
*Solicitor and of Counsel for*
*The Electric Smelting and Aluminum Co.*
Cleveland, Ohio.

[We would regret exceedingly if the phraseology referred to by Mr. McMillin should convey to the minds of our readers generally any lack of recognition or any sense of depreciation of the splendid pioneer work of Mr. Alfred H. Cowles. The article in question was written at the request of the editor by one who has an intimate knowledge of the career of Mr. Cowles, and the qualifications were introduced merely because the expressions affected were explicit statements of fact beyond the knowledge of the editor, and which, since the article bore

no signature, would, without such qualification, have gone on record as facts within his knowledge. To this confession of a lack of that omniscience which tradition assigns to the editor must be joined a keen regret that the time at our disposal did not permit of an inquiry, the results of which would surely have strengthened, rather than weakened as Mr. McMillin would believe—a tribute to one who stands so pre-eminent in the field of electrochemistry.—ED.]

## BOOK REVIEWS.

LEHRBUCH DER ANORGANISCHEN CHEMIE. By Dr. H. Erdmann, Professor of the Institute of Technology of Berlin. Third Edition. 788 pages, with 291 illustrations, 93 tables and six colored tables. Brunswich: Friedrich Vieweg & Sohn, 1902. Price, 15 marks.

To those who read German, are *conversant* with chemistry and wish a concise presentation of the present condition of descriptive inorganic chemistry, including the most recently discovered facts, this fine volume is heartily recommended. Its appearance is attractive, with its fine paper, clear, black print, well-executed engravings, exhaustive table of contents and well-prepared index. The six colored spectrum plates are beautifully executed, and a pocket contains some loose sheets carrying logarithms, constants for calculations of analyses and commonly-used constants, which are very convenient to have at hand.

The treatment of the various chemical compounds is systematic, well balanced and thorough. The synonyms, in old style German, French, English and Russian, are given for all important compounds (Latin might have been added). The most recent discoveries in the condensation of gases, rare gases of the atmosphere, electric furnace compounds, radioactive substances and spectrum investigations are referred to more or less fully, and the information brought up to date in a very commendable manner. In some places the work of foreigners, particularly of Americans, is not accorded the relative importance which it deserves, but that is easily pardonable in a text-book intended for German students—one could hardly expect to find it otherwise.

Turning to the other side of the question, the use of the book as a "Lehrbuch der Anorganischen Chemie," we cannot speak of the volume with such high praise. If the aim of a "Lehrbuch" is simply to fill a student full of facts to make him acquainted with the very latest discovered information, and to feed him upon several half-fledged modern theories, which he is to swallow whole without asking too many awkward questions, then the book may be styled a success. But if a text-book is intended to teach a student to reflect upon chemical fact; to draw from them by logical inferences their most probable hidden meaning; to reason from cause to effect, and from given conditions to probable results; to understand, in short, the esoteric doctrines revealed only to those who search for truth with enthusiasm and a clear, open mind, then this book is, as such a text-book, a lamentable failure.

We cannot but view in the popularity of such a book as a text-book in the German schools a distinct decadence in the teaching of chemistry. The book is singularly free from the plain presentation of simple chemical facts and the deduction of evident conclusions therefrom. In this respect it is immeasurably inferior to Mendelejeff's splendid "Principles of Chemistry." It is appallingly devoid of statements of facts or principles of chemical energetics. The rich domain of thermochemistry, so pregnant with suggestions and explanations of the *why* and *wherefore* of chemical reactions, is practically omitted. In this respect it is immeasurably inferior to Ditte's excellent "Traité elementaire de la Chimie fondee sur la Thermochimie." The relations of electrical energy to chemical energy, their mutual convertibility and the bearing of this on chemical theory and its importance for the progress of chemistry are so scantily touched on as to be almost undiscoverable. What electrochemistry is given in the book is explained in a manner showing that the writer of this part was ignorant of some of the most elementary principles of electrochemistry. His explanations are often misleading, and unworthy of a mere tyro in the science. These are not random statements, but are provable by numerous quotations which could be made.

Concerning the plain, simple principles of chemistry, the book reflects the modern German practice of making a theory and then twisting or distorting one's intelligence in efforts to prove it true, overlooking or ignoring facts which prove it false. This is all the reverse of the true didactic spirit, which should be the soul of every text-book. When the author states, for example, in his preface, that "the so long puzzling difference between metals and metalloids now lies clearly before us, and shows that our old masters had a just intuition in laying these two principal divisions at the base of their division of the elements," we are prepared to find the matter cleared up completely in the text. We find the metalloids therein defined, however, as "elements partly gaseous or easily volatile, partly fixed or infusible, conducting electricity and heat poorly, and not so well cold as hot, and lacking metallic luster." If we now suppose that the unhappy student siezes on this halting definition as something a little better than nothing, how are we to imagine his frame of mind when, among 21 elements thereafter named as metalloids, five are described by the author himself as of "perfect metallic luster!" The book abounds in inconsistencies of a similar nature, which may not, it is true, mislead the chemist who uses the book and who can accept such statements at their real value, but where is meanwhile, our hapless student, who comes to his text-book to be taught.

The great industry and knowledge of the author are proven by the mass of useful information condensed in the book, but the absence of true "teaching quality" in the book, and therefore its distinct inferiority as a *text-book*, are no less plainly in evidence.

JOSEPH W. RICHARDS.

THE OPTICAL ROTATING POWER OF ORGANIC SUBSTANCES AND ITS PRACTICAL APPLICATIONS. By Dr. Hans Landolt, assisted by Dr. O. Schoenrock, Dr. P. Lindner, Dr. F. Schuett, Dr. L. Berndt and Dr. T. Posner. Second edition. Authorized English translation with additions by Dr. John H. Long. 751 pages, with many illustrations. Easton, Pa.: The Chemical Publishing Co. Price, bound in cloth, $7.50.

For those familiar with the second German edition of this work, brought out in 1898, very little need be said, except that the translator has done eminent credit to his work. In general it may be noted, however, that the subject-matter is very happily arranged, and the eye of the reader will readily catch the method of classification that is followed.

The text is introduced without needless historical retrospect or, in fact, any at all; and the symbols, formulæ and equations that are used throughout the book are explained in the first pages instead.

It may be stated that a book devoted so much to theoretical considerations, as this is, should contain as much matter of a practical nature as is given here. For, besides the considerable amount of space devoted to polariscopes and saccharimeters, very complete methods of optical sugar analysis, determinations of camphor, nicotine, cinchona alkaloids, cocaine, etc., are described in detail. The methods for the determination of the sugars are given concisely, yet as complete working methods; and although they are the official methods of the German Government, they are nearly universally adaptable and, we may say, acceptable. For additional methods, the reader is referred to United States Treasury Department bulletins and to other American and English sources.

The only thing that might be said adversely in criticism is

that it would be appropriate for a book of this kind to be better [illegible] especially [illegible] But such a considera- tion is [illegible] the value of the material that is [illegible] the cover.

The work is divided into the following parts: I: General Conditions of Optical Activity. II: Physical Laws of Circular Polarization. III: Numerical Values for the Rotating Power. - Specific Rotation. IV: Apparatus and Methods for the Determination of Specific Rotation. V: Practical Applications of Optical Rotation. VI: Constants of Rotation of Active Bodies. From this it will be seen that the book will appeal very generally to the large body of scientific workers.

## BOOKS RECEIVED.

A Text-book of Inorganic Chemistry. By Dr. A. F. Holleman. Rendered into English by Herman C. Cooper, Ph.D., with the co-operation of the author. New York: John Wiley & Sons. 458 pages, with 84 illustrations. Price, $2.50.

Elementary Chemistry. By F. W. Clarke and L. M. Dennis. New York: American Book Co. 340 pages, illustrated. Price, $1.10.

Vorlesungen ueber Theoretische und Physikalische Chemie. By J. H. van't Hoff. Braunschweig: Friedrich Vieweg & Sohn. Vol. I: Die Chemische Dynamik. 251 pages, illustrated. Price, marks, 6. Vol. II: Die Chemische Statik. 148 pages, illustrated. Price, marks 4. Vol. III: Beziehungen zwischen Eigenschaften und Zusammensetzung. 130 pages, illustrated. Price, marks 4.

Acht Vortraege ueber Physikalische Chemie, gehalten auf Einladung der Universität Chicago, 20 bis 24 Juni, 1901. By J. H. van't Hoff. Braunschweig: Friedrich Vieweg & Sohn. 81 pages, illustrated. Price, marks 2.50.

## ELECTRIC LABORATORY FURNACES.

In the following we give a description of some new forms of electrochemical furnaces which are now being put on the market by Eimer & Amend, New York City, and which are specially designed for chemical work in the qualitative, quantitative and metallurgical laboratories. It is thought that these forms of furnaces will be found extremely useful and convenient for laboratory work, as they give the highest temperatures required, are perfectly controllable and absolutely clean.

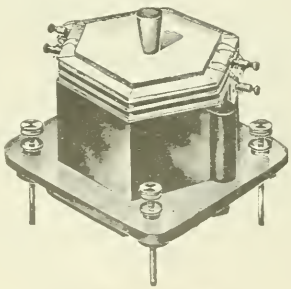


FIG. 1—HEXAGONAL FURNACE.

There is no reduction or oxidation by gases.

The special advantages claimed for these new types of electric furnaces over other electric furnaces are that they are strong and compact, and are built in sections, so that all parts can readily be replaced in case of accident. They are operated at the ordinary electric light pressure of 110 volts, and are not liable to get out of order. The further advantages of these furnaces are that the inside surface is made of smooth material, which does not crumble or crack, and the substance treated can readily be observed. The platinum ware used in these furnaces will last twice as long as in the old-fashioned blast lamp methods. The temperature in these furnaces ranges up to 1,500° C. (2,700° F.); in fact, to the melting point of platinum.

The following are the standard types and sizes: A furnace of square cross section is built in two sizes; the smaller size takes the regular-shape platinum crucibles of 10, 15 and 20 cc. capacity, the available inside space being 1 to 1½ inches by 1 to 1½ inches, the current required being 10 ampères and the voltage 110. The larger size, for 30, 40, 50 and 60 cc. platinum crucibles and Eimer & Amend's new carbon determination apparatus, has an inside space of 2 x 2 inches, the current required being 12 ampères and the voltage 110.

Fig. 1 shows an extra large hexagonal furnace, as used by Professor Landolt and Professor Traube, in Berlin, and others for atomic weight determinations, etc. It has room for

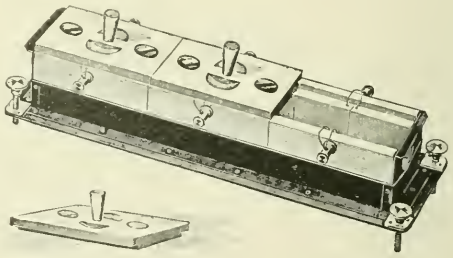

FIG. 2—SECTIONAL COMBUSTION FURNACE.

two platinum vessels for check work, etc., the current required being 15 ampères and the voltage 110.

A muffle-shaped furnace, with front shelf, is made in two sizes. The large size has an inside space width of 3⅛ inches; depth, 3⅛ inches; height, 1½ inches. It takes all regular platinum, incinerating milk and other flat platinum dishes, as well as medium-sized wasting dishes, scorifiers, cupels, etc., the current required being 12 ampères at 110 volts. The smaller size has an inside space of 1¾ inches in depth, 1 inch in width and 11 to 16 inches in height. It is used for determining the fusing point of metals, minerals, enamels and for other small thermic work, the current required being 7 ampères at 110 volts.

Fig. 2 shows a sectional combustion furnace for tubes up to 1 inch diameter, the heating surface being 15 inches in length. The current required is 10 to 15 ampères at 110 volts. This furnace permits of progressive heating from rear to front end, and *vice versa*.

Eimer & Amend also sell an electric furnace of the Moissan type in improved form. The size of the inside space is 6 x 5½ x 5½ inches. It is perfectly adjustable and accessible for experimental arc work, and requires a current of 100 ampères at 50 to 60 volts.

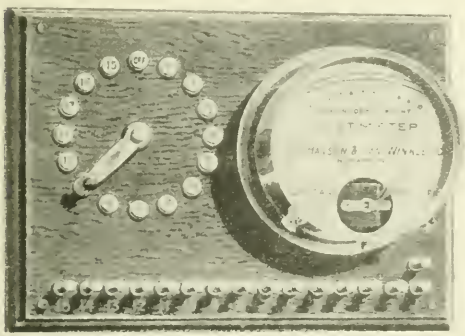
For measuring the whole range of temperature in these furnaces, the improved Le Chatelier's pyrometer, with electric couples with double wires of platinum rhodium, is very suitable. The pyrometers, as placed on the market by Eimer & Amend, are correct indicators of temperature from the normal up to 1,600° C. (3,000° F.), and are tested by the German Reichsanstalt. They are provided with a double scale, a direct reading temperature scale in degrees centigrade up to 1,600, as well as a millivolt scale.

Messrs. Eimer & Amend have also placed on the market an electric heating apparatus for distilling ether from glass vessels without danger. It is provided with a regular Edison incandescent lamp for 110 volts, and is furnished in two sizes, the one for pint flasks and the other for quart flasks.

## VOLTMETER FOR ELECTROPLATING PLANTS.

Great progress has been made in recent years in the methods of electroplating. By careful observation, the practical electroplater has studied the chemical composition of those solutions which are best adapted for obtaining a certain metallic deposit, and at the same time he has learned by experience what are the best electrical conditions—especially the best current density—for obtaining a satisfactory deposit of uniform thickness in the shortest space of time. After he has found once the best electrical conditions, it is only necessary that he should be enabled to reproduce them easily and safely at all times. For this purpose it is of the greatest importance that either the electromotive force between anode and cathode, or the current flowing through the bath, be accurately measured. The ordinary galvanometer is insufficient, and often misleading. Experience has shown that only the very best voltmeters or ammeters should be used in electroplating plants. They should be so constructed as to indicate quickly and accurately any sudden changes in current, and should be direct reading in volts or ampères; and their indications should not be subjected to gradual changes. A sensitive voltmeter will indicate the slipping of belts, short-circuiting in tanks and any irregularity in the power supply.

The adjoining diagram shows the Starrett improved voltmeter, made by the Hanson & Van Winkle Co., Newark, N. J., for the special use of electroplaters. These voltmeters have a



VOLTMETER FOR ELECTROPLATING PLANTS.

scale from 0 to 6 volts and upwards. The scale is divided into 120 divisions, so that each division represents 0.05 volt, and, when in connection with the switch board, the voltmeter enables the plater to study carefully all the requirements which insure good results.

These voltmeters are of the permanent magnet type, and by the process of treating the magnets the manufacturers have succeeded in insuring the permanence of the magnets for years without any appreciable change, unless placed within a powerful magnetic field. For this reason they should not be placed close to a dynamo, nor should a current be passed through them in a reverse direction, as this has a tendency to demagnetize the magnet.

These instruments, as made by the Hanson & Van Winkle Co., are furnished with binding posts for fifteen tanks, thus enabling the operator to use one instrument for any number of tanks up to fifteen by means of a shunt, from which the wires run to each tank. The operator simply moves a switch, and by this arrangement, and in connection with the switch board, he can easily control the voltage for each tank and the current passing through it. It is evident that this arrangement greatly simplifies the methods for exactly reproducing the electrical conditions required for obtaining satisfactory results.

## PERSONAL.

MR. D. R. LOVEJOY, of the Atmospheric Products Co., Niagara Falls, N. Y., has recently sailed for Europe.

DR. R. OGDEN DOREMUS, New York City, recently resigned from the presidency of the Greater American Mining Co., New York.

MR. WILLIAM C. NICHOLS, president of the Nichols Chemical Co., copper refiners, of New York, recently visited the Granby Consolidated Mining, Smelting and Power Co's mines and smelter in the Boundary District of British Columbia.

COL. ALLAN C. BAKEWELL, recently elected president of the Sprague Electric Co., was for the past three years the second vice-president and general manager of this company. In his place, Mr. M. D. Clarence Durland has been elected second vice-president, who, for the last three years, has been assistant general manager of the company.

DR. A. E. KENNELLY has recently returned to Philadelphia from a cable-laying trip in Mexican waters, and has taken up his duties as professor of electrical engineering in Harvard University.

DR. JOHN F. KELLY, of the Stanley Electric Co., has just returned from a long trip abroad.

**American Electrochemical Society.** — The following-named gentlemen have been elected members at the directors' meeting, held November 6th: Erik W. Tillberg, Worcester, Mass.; Geo. W. Patterson, Jr., University of Michigan, Ann Arbor, Mich.; A. V. Knudson, New York; Arthur E. Kennelly, Harvard University, Cambridge, Mass.; C. S. Bradley, New York; Walter T. Taggart, Philadelphia, Pa.; Barthold E. Schlessager, Boston, Mass.; Max Mauran, Niagara Falls, N. Y.; W. E. Goldsborough, Lafayette, Ind.; C. C. Speiden, Summit, N. J.; F. B. Crocker, New York; Charles J. Green street, Fort City, Pa.; Ashmead G. Rodgers, Niagara Falls, N. Y.; F. J. A. McKittrick, Schenectady, N. Y.; Wm. O. Mathews, Dover Bay, Ohio; E. A. Deeds, Niagara Falls, N. Y.; A. T. Lincoln, Urbana, Ill.; J. G. Zimmerman, Madison, Wis.; James L. Ervin, Washington, D. C.; Geo. O. Knapp, Chicago, Ill.; C. E. Freeman, Chicago, Ill.; Charles F. Vaughn, Niagara Falls, N. Y.; Harold Childs Pease, Schenectady, N. Y., and Fritz Haber, Karlsruhe, Germany.

## INDUSTRIAL NOTES.

We have received from Messrs. Baker & Co., Newark, N. J., the tenth edition of their handsomely-illustrated pamphlet, "Data Concerning Platinum." It gives illustrated descriptions of the various types and forms of platinum crucibles, dishes, pans, muffles, spatulas, triangles, filter cones, combustion boats, spoons, electrodes, tweezers, tongs, retorts, baskets, pots, platinum tips for lightning rods, platinum gauze, etc. Some valuable information is given on the use and care and on the cleaning of platinum ware. Special notes refer to platinum stills for the concentration of sulphuric acid and to platinum protective fuses for telegraphic and telephonic work. Several tables at the end of the book will be greatly appreciated by the practical man. They give the weight per foot of platinum wire in troy weights and grams; also the weights per square inch of platinum sheet or foil. Other tables give the number of square inches of platinum sheet and foil per troy ounce, the weight per foot of platinum wire in troy ounces and the number of feet of platinum wire per troy ounce. There are also comparative tables of length, areas and volumes; tables of specific gravities and melting points, a comparative table of wire gauzes, sulphuric acid tables, etc.

THE C. W. HUNT CO., West New Brighton, N. Y., inform us that at the Dusseldorf Exhibition, which has just terminated, the highest award of merit, the gold medal, was awarded to their Hunt conveyor.

# DIGEST OF U. S. PATENTS PRIOR TO JULY, 1902.

*Compiled by Byrnes & Townsend, Patent Lawyers.*
*National Union Building, Washington, D. C.*

*This digest of electrochemical United States patents prior to July, 1902, will be one by classes, setting out for comparison in each class those devices which have the same object, or those methods which seek the same results. In each class the patents will be arranged chronologically. The digest will be complete in the sense of covering every point which is touched upon in the original specification.*

DIAPHRAGM CELLS FOR THE PRODUCTION OF CAUSTIC ALKALI.*

415,644. November 19, 1889; Georg Kerner, of Frankfort, and Julius Marx, Ulm, Germany.

Electrolyzes sodium chloride or "mixed salts of the alkalies or alkaline and other earths, it being known that the current decomposes these salts in a definite order, so that the several bases and acids can be obtained separately." The electrolyte may be heated or cooled. The anode and cathode products are kept apart by a diaphragm, and removed by precipitation or otherwise. When electrolyzing sodium chloride, the dissolved chlorine is removed "by exhausting or drawing, or by forcing air through the apparatus." Says that sodium chlorate gradually accumulates in the solution and is decomposed by the addition of potassium chloride, giving potassium chlorate. When sulphates are electrolyzed, removes the sulphuric acid from the anode compartment by the addition of calcium carbonate, phosphate or chloride. Converts the caustic soda produced in the cathode compartment into a bicarbonate by the injection of carbon dioxide; or may add magnesium carbonate or carnallite to produce a double carbonate, or may produce a double carbonate of sodium and zinc. Afterward decomposes the sodium bicarbonate with caustic soda. Decomposes the double carbonates by boiling or passing steam through them. May effect the precipitations in the electrolytic cell or in separate vessels, returning the residual liquors after enriching them with salt. Causes the anode and cathode solutions to flow in opposite directions, to diminish loss by re-combination.

442,334. December 9, 1890; Isaiah L. Roberts, Brooklyn, N. Y.

Anode, a compressed mixture of retort carbon and ozokerite. Surrounds anode by a mass of finely-divided anthracite coal, held in a bag of cotton, strengthened by asbestos or wire gauze. Gaseous anode products and any overflow escape through a layer of granular carbon and a lateral pipe at the top of the bag, the neck of which is sealed by asphalt or tar. Iron vessel serves as cathode.

442,396. December 9, 1890; Isaiah L. Roberts, Brooklyn, N. Y.

Electrolytic vessel, consisting of an inner and outer wooden box, with an intermediate space filled with tar or asphalt. Walls of anode compartment of glass or slate. Diaphragm of asbestos cloth, between asbestos boards, and inclosed in cotton cloth, the whole treated with sulphuric or hydrochloric acid. Anodes of carbon, or an alloy of lead, antimony and mercury. Cathode, copper.

442,494. December 9, 1890; Isaiah L. Roberts, Brooklyn, N. Y.

Apparatus similar to 442,334, except that a glass cylinder extends from the neck of the bag down into the packing of coal dust.

450,103. April 7, 1891; Ernest Arthur Le Sueur, Ottawa, Canada.

Vessel, a shallow open tank, containing a number of anode bells of stoneware. Each bell is closed at its lower end by a diaphragm of vegetable parchment, beneath and in contact with which is the cathode, consisting of a number of sheets of wire gauze riveted together. One rivet of each cathode extends down into a mercury cup in the bottom of the tank. Cathode connections lead to each mercury cup. A single cathode may underlie all the bells. The tank may be of iron, and also act as cathode. Each bell is supported in the tank in a slightly inclined position, to facilitate escape of hydrogen from the cathode. Each bell is nearly filled by an anode consisting of a large number of carbon rods, secured at their upper ends in a lead plate and extending down nearly to the diaphragm. Through each bell pass supply tubes, which dip into the electrolyte, and an outlet for chlorine.

450,104. April 7, 1891; Ernest Arthur Le Sueur, Ottawa, Canada.

Inclined anode bell of earthenware, supported on the bottom of an open tank. Lead tubes pass through the top of the bell, and serve both as supports for the anode and conduits for introducing brine and removing chlorine. Lower end of bell closed by a diaphragm and wire gauze cathode. Diaphragm clamped to lower edge of bell by a metal ring, within which sufficient hydrogen accumulates to press diaphragm against lower edge of bell, preventing leakage. Electrolyte in bell maintained at a somewhat higher level than outside. Automatic device cuts off electric current in case the diaphragm ruptures.

468,880. February 16, 1892; Ernest Arthur Le Sueur, Ottawa, Canada.

Anode bell has an outer overflow passage to indicate level of liquid within. Anode supported in bell by a central stem, having a passage for introducing brine. Upper end of stem surrounded and supported by an inverted cup, having sealed chlorine outlet. Cup supported on bell by adjusting screws or wedges.

480,491. August 9, 1892; Elisha B. Cutten, New York, N. Y.

Vessel of iron serving as cathode. A horizontal glass plate near bottom of vessel supports a glass trough, within which is a carbon bar imbedded in insulation. Vertical anode rods, arranged in a row, are screwed into the carbon bar at their lower ends. End of carbon bar extends out through vessel and carries anode terminal. A transparent glass bell incloses upper ends of carbon rods. An annular sheet-metal hood fills the space between sides of the vessel and bell, its flanges dipping into the electrolyte. A pipe for removing hydrogen leads from this hood to a suction pump. A pipe for removing chlorine leads from glass bell to a suction pump. A body of solid salt is maintained within the vessel, resting on the glass plate near the bottom and extending up to the upper ends of the anode rods. An inclined gutter at the bottom of the vessel serves to remove caustic. A passage for the introduction of strong brine extends through the carbon anode bar, and branch ducts open up between each pair of anode rods. Inside of iron vessel coated with varnish to a point below lower edge of glass bell. May electrolyze calcium or magnesium chloride.

481,407. August 23, 1892; Farnham Maxwell Lyte, London, England.

Production of caustic alkalies and chlorine. First, produces sodium ferrate, nitric oxide and oxygen by heating a mixture of sodium nitrate and ferric oxide; second, boils the ferrate with water, producing caustic free from iron and ferric hydrate; third, decomposes the ferric hydrate by heat, producing ferric oxide, which is returned; fourth, produces nitric acid by adding air and water to the nitric oxide and oxygen from the first reaction: fifth, combines the nitric acid with litharge to produce lead nitrate; sixth, decomposes the lead nitrate with sodium chloride, producing lead chloride, which is melted and electrolyzed, and sodium nitrate, which is returned. Converts the electrolytic lead into litharge, which is returned.

## STORAGE BATTERY INVENTION AND MANUFACTURE.

In this issue we print several articles referring to storage battery construction and practice. The galvanic battery was the first apparatus invented in the subject of electrochemistry, and the manufacture of lead storage batteries was the first great electrochemical industry. Before the introduction of the more recent electrochemical processes, in which the electric current is the means for producing chemicals, it had long been known that chemical energy is the most efficient form of energy for storing electrical energy. The storage battery has now become a necessary accessory to electric lighting and railway plants, like dynamos and other electrical apparatus.

Stationary batteries for central station work represent at present 75 per cent. of all the storage batteries manufactured. For this purpose, the position of the lead cell seems secure. In the long series of years since the lead cell was introduced into practice, many inventors have contributed to its improvement, although the cell on the whole is the same as in the days of Planté and Faure. Battery design is now being standardized. For central station work, the manufacturer no longer aims to invent a new battery, but only to increase the reliability in practice and to diminish the cost of the present lead cell.

In recent years, however, the progress of automobilism has set a new problem to the battery designer; that is, the invention of a battery of small weight and small size. The electric motor is conceded to be the ideal motor for an automobile, but the electric storage battery is far from being ideal for this purpose. The main trouble is, of course, that the lead cell is too heavy. Nevertheless, with the present batteries in the market, experience has conclusively proven that the electric automobile has a future.

Some exact data, given in this respect by Mr. Hugh Rodman in his recent American Electrochemical Society paper, are of great interest. The commercial life of lead plates in truck or cab service is about 15,000 to 20,000 miles for negatives, 12,000 miles for Planté positives and 6,000 miles for pasted positives. In other words, a 4 or 5 ton truck, running 20 miles per day for three hundred days in a year, requires new positive plates once in a year, or once in two years, according to the type of plate used. Cabs and lighter wagons have about the same life, with a capacity of 40 to 100 miles on one charge. Work done under these conditions—actual work reduced to dollars and cents—has shown that the electric wagon, as it is at present, gives better city service than can be gotten from gas or steam or horse.

Under these conditions, Mr. Rodman's conclusion is evidently justified, that if a better battery than the present lead cell was available, it would control practically all city traffic not on rails. This shows the importance of the problem. It can be solved either by devising an entirely new battery with

materials other than lead [illegible] by improving the present lead cell. Mr. Edison has adopted the first means in his celebrated [illegible] cell. His [illegible] highly interesting in several respects; that it is greatly to be regretted that authoritative statements concerning the progress of its manufacture is not available. On the other hand many skillful workers try to improve the lead cell by special means, and endeavor to adapt it to automobile practice. There is activity all around, and for this reason we trust that the descriptions of automobile batteries of American manufacturers, of which we print the first part in this issue, may be of interest to our readers. We may add that these descriptions are *ex parte* statements, based upon the information given to us from the manufacturers.

## CALCIUM CARBIDE AND ACETYLENE.

On another page of this issue we print a review of the present conditions of the calcium carbide and acetylene industries. While the commercial crisis of these industries in Continental Europe is not yet over, we are glad to note that both of these industries show signs of healthful and steady growth and progress in this country.

These industries may be considered as a typical example of the progress made by electrochemistry in conquering Nature. They represent a case of storing up the energy which is given us from Nature in waterfalls, in the form of chemical energy (calcium carbide), which may be converted afterwards into light or mechanical energy (acetylene light and motors).

Calcium carbide is universally made by water power, for the simple reason that the cost of power is a very important item in the total cost of the product, so that cheap power is essential for commercial success. Water power always existed, but was not utilized until the development of hydroelectric stations began. The electric power, generated from water-power, can conveniently be converted into light and mechanical power, and there is the great advantage that, if only a transmission line is installed, the electric power may easily be transmitted to another place and there be utilized for lighting and power. But in these transmissions and conversions of energy there is one very important thing impossible: the energy cannot be stored up.

To store up energy efficiently, it is necessary to convert it first into chemical energy. This has long been recognized by the central station engineers when they installed storage batteries, to charge them at times of light load and to discharge them at times of full load. The efficiency of this system and its economical advantages are so well recognized that this arrangement is now generally used. Now, to charge a battery when the load in the station is light means simply to store up the surplus of electrical energy in form of chemical energy, and when the battery discharges, at times of full load, this stored up energy becomes again free and available for light and power purposes. This conversion and reconversion of different forms of energy is necessarily accompanied by losses, nevertheless experience has proven beyond doubt that the total system is effective and economical.

What is done on a small scale by the storage batteries with the surplus of electrical energy in central stations is done on a much larger scale by the calcium carbide and acetylene industries with the energies of the waterfalls. The energy of the water is not the energy of the water *per se*, but that of the *falling* water; hence if it is not used or stored up just at the moment when the water falls down, the energy is lost. In hydroelectric power stations we have the means of converting the mechanical energy of the falling water into electrical energy, but, in order to store it up for future use, it is to be converted into chemical energy. This is done in the manufacture of calcium carbide in the electric furnace.

In order to make the whole process successful, it is, of course, necessary that the chemical compound which is produced in the furnace is of such a nature that the energy stored up in the same can easily be set free again and rendered available for useful purposes. This is decidedly the case with calcium carbide, as, by reaction with water, it yields acetylene. The advantages of the whole process are clearly evident. It is not astonishing that the progress of the calcium carbide industry has been rapid, but it is also evident that the progress of the calcium carbide industry must be necessarily associated with increase in the use of acetylene.

We print in this issue some remarks made by Mr. James Swinburne in his presidential address to the British Institution of Electrical Engineers on the real value of water-powers for electrometallurgical work. He thinks there is often an exaggerated value attached to water-powers, and that a water-power is useful only if it is at a place where it is wanted and needed commercially. This is exactly correct, but in his further remark, that as a rule water-power is not where it is wanted industrially, Mr. Swinburne seems to have the conditions of England merely in view. The conditions in this country are different. Niagara Falls, Massena and Sault Ste. Marie are near the great waterways and railways; transportation is cheap. These plants are commercially in touch with the commercial centers of this country. It is just for this reason that the prospects of a healthful and rapid development of electrochemical industries at those places are bright. The development of Niagara Falls as an industrial center has been an object lesson in this respect, and we trust the other great American water-power plants will equally become centers of electrochemical activity.

## FREE IONS.

When the theory of electrolytic dissociation was first put forward, it was not received with open arms by the chemical public at large; it was rather ridiculed and laughed at. In return, the promoters of this theory emphasized their standpoint with stubbornness and boldness. This explains some rather unfortunate terms used in the nomenclature of the theory. In order to emphasize that a salt when dissolved in water is in a different molecular condition than before it was dissolved, and that its two kinds of ions are in some respects independent of each other, the term dissociation was borrowed from the chemistry of gases and the term "free ions" was coined. While it was pointed out that electrolytic dissociation is essentially different from ordinary chemical dissociation, yet the old term was adopted for a new conception. The meaning of the ionic theory is now better understood, and no

serious misunderstandings may be feared at the present time from the use of the term electrolytic dissociation. Nevertheless it may be worth while to analyze briefly the ideas underlying the adoption of this term, and to show in which respects ions are "free" from the point of view of the dissociation theory.

An absolutely indisputable way of getting at the answer, and a way which excludes any misunderstanding, is to consider the differential equations, assumed by the theory of electrolytic dissociation, to govern the whole ionic mechanism. These equations, as given by Nernst (and later, in an elegant mathematical form, by Planck), are the foundation of his theories of diffusion and of concentration cells, and state exactly the sense of the theory, and there can be no dispute about their meaning.

Two different kinds of forces are assumed to exist in the interior of an electrolytic solution—osmotic forces and electrostatic forces. The osmotic forces are due to concentration differences existing in the solution. Differences of concentration at different places in the solution produce different osmotic pressures, and they tend to equalize, just as would be the case in the interior of a gas if different pressures should exist at different places, the law of the osmotic pressure and the law of the gas pressure being identical. The second kind of forces—the electrostatic forces—are due to the electrostatic charges of the ions. Each monovalent gram ion has a charge of 96,540 positive or negative coulombs, and the attractions and repulsions between the different ions are assumed to follow strictly the ordinary laws of electrostatics. If we consider any point in the interior of an electrolyte, then there is a certain force acting there, and this force is the resultant of the osmotic force and the electrostatic force existing at this point.

Now, let this total force be given at any point of the solution, and also the numbers of different kinds of ions at that point, what will happen? The theory assumes that all the positive ions will move in one direction of the line of force, and all the negative ions in the other direction. The theory further assumes that each ion tends to travel independently of the others, the speed of each ion being simply its "mobility" (Kohlrausch) multiplied by the acting force at that place. As the mobilities of the different kinds of ions are different, they would travel with different speeds, and the so far independent of each other. But nevertheless—and this is a very important point, clearly brought out in the equations of the theory—there is in any given space inside of a homogeneous solution exactly the same number of positive and of negative ions. At no space inside the solution is there free electricity.

We know there is a certain energy required for decomposing an electrolyte, say hydrochloric acid, between inert electrodes. In the sense of the theory of electrolytic dissociation, this energy corresponds to the change of the H and Cl ions into atoms. This emphasizes the fundamental difference which the theory makes between ions and atoms.

To sum up, the theory assumes a "dissociation" into ions, not atoms. The characteristic feature of each gram ion of the valency $n$ is that it is charged with $n \times 96{,}540$ coulombs. Each kind of ion has a characteristic mobility, determining the speed at which it travels under a given force. Finally, a certain energy corresponds to the change of an atom to an ion, and this energy, when measured in calories, is called the ionization heat. It is thus fairly clear that this electrolytic dissociation is essentially different from chemical dissociation.

It is therefore a pity that the promoters of this theory did not propose the concise and clear term "ionization," instead of the ambiguous term "electrolytic dissociation." Many misunderstandings would then have been avoided. Concerning the justification of the term "free ions," it all depends on what we mean by "free."

While the whole idea of the dissociation theory, when first proposed, was decidedly novel, yet the several assumptions made concerning the properties of the ions were not so. That the ions travel independently with different speeds has been known from the time of the investigations of Hittorf and Kohlrausch. Views approaching the hypothesis of dissociation had been expressed by Clausius. That each ion carries a certain charge had also been known for a long time. To quote only two authorities: "If we adopt the atomic theory or phraseology, then the atoms of bodies which are equivalent to each other in their ordinary chemical action have equal quantities of electricity naturally associated with them" (Faraday), and, "The same definite quantity of either positive or negative electricity moves always with each univalent ion, or with every unit of affinity of a multivalent ion" (Helmholtz, 1881). Nevertheless Arrhenius' famous paper was decidedly original, because he suggested distinct methods for determining the exact number of the ionized molecules and because by his theory he endeavored to save the general validity of Van't Hoff's application of the gas laws to solutions. We do not belittle his work in the least if we must admit that, in the light of more recent investigations, it becomes quite questionable whether Arrhenius' methods for determining the number of ionized molecules are really correct.

It is even quite doubtful whether the whole conception of the condition of the ionized solution is really so simple as the theory assumes. True, the theory is claimed to be strictly correct only for infinitely dilute solutions, and difficulties resulted generally from experiments with more concentrated solutions, so that they should not be used as an argument against the theory. That the theory deals with an ideal case, i. e., infinite dilution, is absolutely no reason to belittle it. It is the same thing with the theory of alternating current phenomena, which starts from the assumption of sine-curved waves which scarcely exist in practice.

Finally, we may say that some of the difficulties in the conception of ions will disappear when the more recent assumption of an ion being a compound of an atom with an electron becomes more general. Many points which are otherwise not clear are thus explained. The ionization heat is simply the formation heat of an ion from the atom and the electron. Above all, the theory becomes so simple that it recommends itself to the practical man. Every chemist uses in his calculations the conception of atoms and molecules, because they simplify the conceptions and calculations. For exactly the same reasons the "atomic theory of electricity," that is, the electron theory, recommends itself to the practical electrochemical engineer.

## WESTON INSTRUMENT PATENT DECISION.

While we are going to press we are informed that Judge Lacombe, of the United States Circuit Court of the Southern District of New York, has handed down a sweeping decision in an infringement suit instituted by the Weston Electrical Instrument Co. He sustains two Weston patents for alternating-current instruments in all points, one being a re-issue patent, dated June 28, 1892, the date of the original application being January 18, 1890, and the other, a patent subsidiary to this, dated March 8, 1892.

## JAMES SWINBURNE ON WATER-POWER AND CARBON CELLS.

Our English contemporaries just begin to reprint Mr. James Swinburne's presidential address to the (British) Institution of Electrical Engineers. The London *Electrician* editorially characterizes it as "one of the finest presidential addresses that it has been the good fortune of the Institution to listen to." To our readers Mr. Swinburne's remarks on the utilization of water power and on the prospects of carbon cells may be of special interest.

Mr. Swinburne thinks that an exaggerated value is vulgarly attached to water-powers. "As a rule water-power is not where it is wanted industrially. In the nature of things, water-powers are generally in hilly countries, and are seldom near the sea. The result is that a water-power as a rule cannot command the same price as steam or gas, because it is not where it is wanted. The idea in starting many of the water-power stations also was that works which needed power would come and settle near. As a matter of fact, the cost of power is a much smaller item in most industries than is generally supposed, and it does not pay to start a works in an otherwise not perfectly suitable locality simply for the sake of cheap water-power. . . . It may be said that in electrometallurgical processes the whole cost is practically the electrical energy, and so carbides, aluminum and electrolytic soda and chlorate of potash will be made at water-powers. Even this, however, is misleading. Carbides and aluminum are generally made at waterfalls, and chlorate nearly always is. Electrolytic soda and bleach are made at water-powers, but are also made extensively by steam-driven plants. Against the cheaper power, we have to put extra carriage for materials and for coal, which is often needed in addition; and extra carriage for finished products, and very often extra cost of labor, as labor is often dear and bad in water-power districts. Let us take, as an example, calcium carbide. The general idea is that the electrical energy is practically the whole cost of the carbide, but, taking present practice and the price of carbide at £13 10s. a ton, doubling the cost of power, instead of nearly doubling the price of the carbide, only increases it a little more than 10 per cent. Difference in local cost of coke, lime and labor, coupled with cost of carriage, may thus easily be of more importance than cheap power, even in such a case as calcium carbide, which is an electrical furnace product in which, at first sight, the power seems to be the main element of cost. In the case of electrolytic caustic and bleach, for 1 ton of caustic and the corresponding bleaching powder, the electrical energy, taken at £2 10s. per kilowatt year, a low water power cost, comes to about 17s. 6d. The caustic and bleach sell for about £20, according to a varying market. Doubling the price of power, therefore, increases the price some 5 per cent. It may thus easily pay to use much more expensive power if the other conditions are more favorable. Steam-power, for instance, will cost three or three and a half times as much, and yet it pays to make electrolytic caustic and bleach in England where the other conditions are all favorable. It is not, therefore, the want of water-power that has kept the electrolytic industry back in this country. For a water-power to be really valuable, it should be near a source of material on the sea, and should have a great head of water, so that the capital cost of development is small. Such a water-power is very valuable—to the landlord."

"A blast furnace is more valuable than a water power. There are plenty in England, but the owners, who have been wasting the gas up to now, will not give it away; they will want rent, so that it will only just pay to use his gas rather than make it. The electrical industry thus does not gain, but the iron masters do."

Mr. Swinburne's remarks on carbon cells are as follows:

"For many years 'electrical energy direct from coal' has been the dream of the electrochemist. That is to say, he has dreamed of an electrolytic cell in which the consumed electrode is carbon. The best way to realize the difficulties of this problem is to consider it solved and see what it means. The carbon must be in contact with an electrolyte, and the electrolyte must either be in contact with a second electrolyte, which wets the other electrode, or must itself be in contact with that electrode. This second electrode must almost certainly be metal, as there are no other non-metallic conductors available. The electrolyte in contact with the carbon must be a salt of carbon or must contain a salt of carbon, or it must contain another salt whose positive radicle can be replaced by carbon. Such compounds as the hydrides, nitride, oxides, chloride, bromide or the sulphide or silicide of carbon are not salts in the electrolytic sense. Carbon forms part of the electropositive radicle in the organic radicles, and part of the electronegative radicle in the cyanogen compounds, but it is never a radicle by itself. To sum up the matter shortly in the light of modern theory, carbon never forms ions, and has, therefore, no solution pressure, and can, therefore, give no e. m. f. At ordinary or moderate temperatures carbon is practically inert. Oxidizing agents will attack some forms lightly, and sulphuric acid will attack it. In this latter case the formation of water and its combination with the acid is the determining factor. At high temperatures, oxygen, sulphur, silicon, and to some extent nitrogen and many of the metals, combine with carbon, but there is no dissociable salt of carbon formed. The carbon cell thus seems impossible. Such schemes as Mr. Reed's, ingenious as it is, is not a solution of the problem. It would be simpler to reduce zinc oxide with the carbon, and then put it in a zinc cell. It is hardly necessary to discuss thermopiles or thermo-magnetic engines as possible economical producers of electric power."

## OVERVOLTAGE.

In the recently-issued second volume of the "Transactions of the American Electrochemical Society," page 83, some of the remarks made by Dr. F. Haber, in the discussion of Mr. Weightman's paper, appear somewhat ambiguous, as Dr. Haber had no opportunity to revise the stenographer's report. As the matter is of some interest, we give herewith the substance of a letter recently addressed by him to the president of the Society.

Dr. Haber intended to say in those remarks that overvoltage, which is a newly-coined word for an old, well known phenomenon, refers to the fact that it requires a higher voltage to develop gases on certain electrodes than would be expected from the thermodynamic theory. From his point of view, it means that the gaseous compound is not formed from the ions at one single step, but that an intermediate product is first formed, as, for instance, in the case of hydrogen it may be an alloy of that gas and the metal of the cathode, or a solution or occlusion of hydrogen in or at the metal of the cathode. He emphasized the idea, that the properties of this intermediate product were responsible for the phenomenon, although he had to admit that we are not yet quite able to make such a definite statement of this property as will cover the ground perfectly. He gave as an example the behavior of mercury as cathode in dilute sulphuric acid to explain this subject.

## SODIUM CHLORID IN ELECTROLYTIC CAUSTIC ALKALI.

By Clinton Paul Townsend.

In a former paper (Electrochemical Industry, Vol. I, page 23) the writer discussed in a general way the influence of the movement of the products of electrolysis upon the course of the reaction in the electrolysis of sodium chlorid solutions, and referred to the several types of cell which have been proposed or used, considering these types particularly from the point of view of the means employed for checking such movement between the respective compartments of the cell.

In every electrolytic cell capable of producing caustic soda such means are present; in their absence, the cell passes into the type adapted for the production of bleach liquor or chlorate. The idea of means differs, of course, very widely, and may comprise a stationary septum of mercury entirely impervious to a liquid; a moving body of mercury; a diaphragm, one side of which may be unsubmerged in order to allow the product to flow freely from it; a definite direction and rate of liquid flow, or merely such disposition of parts as will avoid or minimize agitation by escaping gases, convection currents or the feed and discharge of the electrolyte.

The purpose of the present paper is to consider a single aspect of this question, viz.: the movement of undecomposed sodium chlorid into the caustic compartment.

Sodium chlorid is soluble in caustic soda solutions to a degree dependent on the concentration of the hydroxid. A solution containing 10 grams of caustic soda per litre is capable of dissolving 308 grams of sodium chlorid, while a solution containing 640 grams of caustic per litre can dissolve only 18 grams of salt. The solubilities of salt in caustic of various concentrations at 20° C. have been accurately determined by F. Winteler (*Zeitschrift fur Elektrochemie*, 7, page 360).

Of the several general types of cell mentioned above, one only is capable of yielding a caustic solution absolutely free from dissolved chlorid. This is the cell, as originally suggested by Vautin and modified by Kellner, and later by Edser, wherein the caustic compartment is separated from the remainder of the cell by a stationary septum (cathode) of mercury, which is pervious to metallic sodium, but not to water or compounds in solution therein. The term "stationary" is here employed to indicate that the mercury is not transferred bodily from one point to another during the operation. An internal movement of the mercury, to aid the slow process of diffusion in transferring the metal from the surface of deposition to that of oxidation, is, of course, essential, since otherwise both the capacity and the efficiency of the arrangement would be very low. The provision of means which should entail neither undue complication of parts nor too great expenditure of energy for producing a sufficiently rapid transfer of the dissolved alkali metal would make this cell the ideal one for the production of pure caustic solutions.

If the body of mercury be moved continuously or intermittently between decomposing and oxidizing compartments beneath a depending partial partition, the mercury itself constituting a seal between the respective solutions, the quantity of chloride which will be transferred from the electrolyzing compartment to the caustic side and the quantity of caustic transferred in the reverse direction depend largely upon the exposed surface of the mercury and the velocity imparted to it. It is essentially a transfer by wet surfaces, and is not considered to affect seriously the commercial operation of the cell. It is a phenomenon entirely different from that to be considered here.

Let us consider next a construction comprising two electrodes of opposite polarity, an outflow opening adjacent to each and a single inlet for the electrolyte, such inlet being situated between the electrodes and serving to produce a flow of the electrolyte in opposite directions from the intermediate part. It will be clear that if the rate of flow of the electrolyte be sufficient to overcome the backward diffusion of the reaction products and their movement caused by other agencies, the cathode liquor will consist only of the hydroxid and chlorid of sodium. If the current efficiency reaches 100 per cent., which can be measurably attained under these conditions with sufficiently rapid flow, the composition of the liquid flowing past the cathode can be readily calculated. A quantity of the sodium chlorid equivalent to the current used has yielded caustic according to the equation

$$NaCl + nH_2O = Cl + H + NaOH + (n-1)H_2O;$$

the proportions of chlorid and hydrate being molecular, but a concentrating effect due to the decomposition of water supervening. The exact composition corresponding to any given current and liquid flow and composition of electrolyte is, of course, readily determined.

The above construction fairly represents in principle the type of "gravity cells." If the flow of the liquid be rapid, assuming that the maximum permissible current density is employed, the current efficiency will be high, but the cathode lye will be low in caustic and high in salt. For the withdrawal of the products and the prevention of secondary reactions, a certain minimum rate of flow is essential, and this rate of flow is, in the cell constructions as yet proposed, too high to admit of thoroughly satisfactory concentrations of caustic.

The ratio which the quantity of salt electrolyzed bears to the total quantity passing the cathode is the decomposition efficiency. There is, at moderate rates of flow, in a cell of the type above referred to, an inverse relationship between decomposition efficiency and current efficiency; and a perfect decomposition efficiency, at even moderate current efficiency, will always be impossible in the absence of means for removing the cathode products from the field of electrolytic decomposition absolutely at the instant of their formation.

The above considerations will make clear the true function and character of the diaphragm in a caustic cell. It is essentially a device for controlling and equalizing the forward movement of the electrolyte and for retarding the backward movement of the products of electrolysis, and thereby permitting the establishment of a new and lower minimum flow for their removal. It is in no sense to be considered as a septum capable of permitting the passage of the electric current, but of preventing the diffusion and recombination of the products in stationary bodies of electrolyte. Yet this latter conception seems to be the common one among workers in the art. The new minimum thus established corresponds to higher concentrations of caustic with equal current efficiencies.

A solution of sodium chlorid saturated at ordinary temperatures corresponds approximately to the formula $NaCl + 9H_2O$. Complete decomposition proceeds according to the equation

$$NaCl + 9H_2O = Cl + H + NaOH + 8H_2O,$$

the per cent. of caustic in the resulting lye being theoretically 21.7. It would appear, therefore, that this figure should be regarded as the maximum concentration of caustic obtainable by direct reaction from any electrolytic cell which depends upon the water of the electrolyte for oxidation of the metal sodium. It is interesting, therefore, to observe that this concentration is easily exceeded; that no sharp break in current efficiency occurs at or near this figure, and that cathode lyes of the approximate caustic content above noted have been found to contain a quantity of undecomposed salt which corresponds nearly to their saturation point.

The cell from which the following curves were obtained need not be further described than by the statement that it was provided with a thin permeable diaphragm, adapted to restrain and equalize the flow of the electrolyte and a cathode whose form fitted it to serve as a surface for the rapid discharge of the cathode products. The annexed diagram (Fig. 1) shows in solid lines (A) the percentages of caustic and (B) the percentages of undecomposed salt. The broken curve (C) indicates the saturation curve of salt corresponding to the caustic

found. The analyses from which the curves were plotted were made at forty-minute intervals.

It will be noted of these curves that the caustic attains approximately the supposed theoretical maximum above referred to, and that the undecomposed salt is present nearly to saturation of the caustic. It will be further noted that there is apparently a strong concentration effect, inasmuch as the sum of the salt found, and the salt equivalent of the caustic, is far in excess of the saturation point for aqueous solutions of

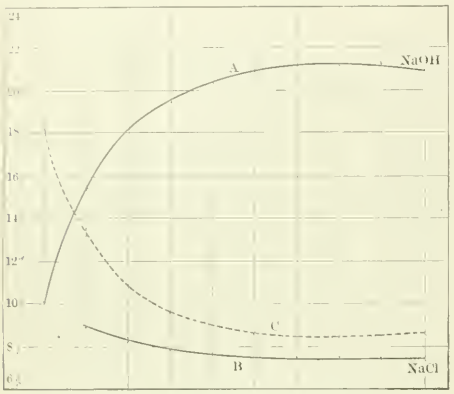

FIG. 1.—SODIUM CHLORID ELETROLYSIS.

salt. This is, without doubt, due in part to concentration of the cathode liquor by loss of water with the escaping hydrogen, in part to the cathodic reduction of hypochlorite and in part to the movement of the salt through the diaphragm under the influence of the difference of osmotic pressure upon opposite sides of the membrane.

These results suggest at once a query as to the relative proportions of caustic and salt in the cathode product of the electrolysis of more dilute sodium chloride solutions. A solu-

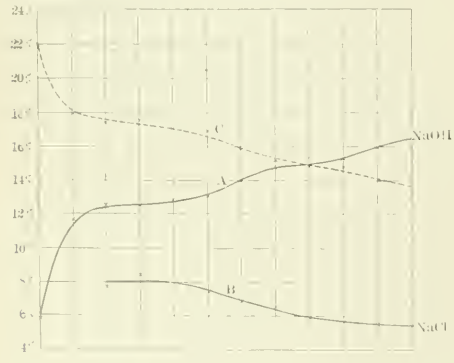

FIG. 2.—SODIUM CHLORID ELECTROLYSIS.

tion corresponding approximately to the formula $NaCl + 15H_2O$ was electrolyzed. The theoretical concentration of caustic obtainable from such solution, if completely electrolyzed without concentration, is 13.7. The results are shown in Fig. 2, curves A, B and C representing, as before, percentages of NaOH, NaCl and the saturation curve of salt in caustic respectively.

The irregular form of the caustic curve in this case, indicating as it does an intermittent progress to concentrations considerably exceeding those theoretically attainable without loss of water, is not easily explained, inasmuch as the electrolyzing current was maintained substantially constant, and the rate of flow of the solution underwent no corresponding variations, but diminished slowly and regularly from the beginning to the end of the experiment, which occupied 440 minutes. The analyses in this, as in the other cases, were made at intervals of forty minutes. The broken curve C, representing as it does merely the percentages of salt required to saturate the caustic of the curve A, is substantially the reverse of the latter. Most peculiar, however, is the close parallelism between the curve B, representing the saturation line, and the curve C, representing actual salt content. The latter parallels the former, the interval between them corresponding to about 9 per cent. of salt.

The electrolyte was then diluted to the composition $NaCl + 18H_2O$ and the curve secured, as shown in Fig. 3. This solu-

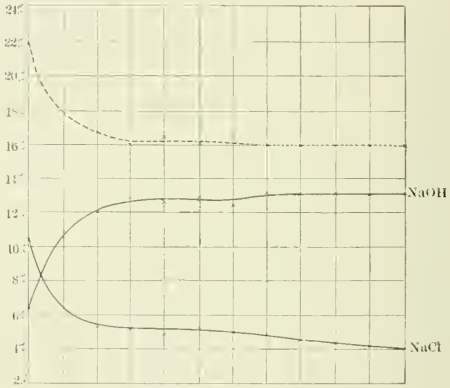

FIG. 3.—SODIUM CHLORID ELECTROLYSIS.

tion, completely converted into caustic without further concentration than is called for by the reaction, should yield a liquid containing 11.6 per cent. NaOH. As in the previous case, the concentration obtained is considerably in excess of this figure. The salt curve B again nearly parallels the saturation line C, but the interval between them is now approximately 11.5 per cent.

These results clearly show the controlling influences of the concentration of the electrolyte upon the salt content of the resulting caustic. In a subsequent note the writer hopes to discuss the character and limits of this relationship.

The history of the development of the diaphragm type of caustic cells is one of the most interesting chapters of electrochemistry, but it is largely a story of individual failure. It is usual to regard the defects of high resistance, low concentration and purity of product and rapid deterioration in use as inherent in cells operating by this method, but the whole tendency of recent work is to the effect that such is not necessarily the case. A diaphragm adapted to perform its true and proper function need neither offer high electrical resistance nor be perishable; it is only when the work of maintaining a separation of the products of electrolysis—a result which should be secured by other means—is imposed upon the diaphragm that it becomes an inefficient tool and a troublesome element of the cell.

INTERNATIONAL CONGRESS FOR APPLIED CHEMISTRY.—The arrangements for the meetings of the electrochemical section of this congress, to be held in Berlin next year, are in charge of the German Bunsen Society. Besides the papers to be read, it is intended to have experts present reports on the following subjects: The scientific and technical problems of the chemistry of calcium carbide; electrochemical methods for preparing organic compounds; the problems of physical chemistry in the manufacture of sulphuric acid; fixation of atmospheric nitrogen.

## PIONEERS OF ELECTROCHEMISTRY—IV.

### HAMILTON YOUNG CASTNER.

Although the subject of this sketch is no longer among the living, yet it is none the less highly appropriate that his name should be placed here among the pioneers of electrochemistry.

Born in Brooklyn, N. Y., on September 11, 1859, educated at a private school, and entering Columbia College School of Mines as a student in chemistry in 1875, Mr. Castner had the great good fortune to come into personal contact during three industrious years with Dr. Chas. F. Chandler, and the warm friendship between teacher and student continued all through his subsequent career. In fact, as a last tribute to its successful student, the School of Mines is about to place in the corridor of its new home, on Morningside Heights, Havermeyer Hall, a bronze tablet commemorative of his name and achievements.

Leaving college in 1878, Mr. Castner established himself as an analytical chemist, and in his spare time was constantly experimenting with chemical and metallurgical processes. He invented an improvement in the manufacture of bone black. Later he became enthusiastic over the possibilty of cheapening the cost of aluminum, which, in 1880, was selling at $12 per pound, and he directed his experiments towards finding a cheaper method of producing sodium. His laboratory, on West Twentieth street, three floors high, was filled with furnaces and apparatus, and out of it emerged, in 1886, a successful process for producing sodium by reducing caustic soda by a mixture of iron and carbon, in steel pots, in a regenerative gas furnace. Instead of costing $2 per pound, sodium was thus obtained for about 20 cents per pound, and the way to cheaper aluminum was open. Each pound of aluminum requiring 3 pounds of sodium to reduce it, the saving on the former was easily $5 per pound. The United States patent for this process is 342,897, of June 1, 1886.

H. Y. Castner

Going over to England, Mr Castner put up an experimental furnace in London, and, on proving his claims to the satisfaction of Sir Henry Roscoe and other chemical experts, the Aluminum Co., Ltd., was formed, and the erection of large works commenced at Oldbury, near Birmingham. (This town is the writer's birthplace, and it was at this time that the writer's personal acquaintance with Mr. Castner began, an acquaintance which, during twelve years, ripened into sincere friendship.)

In connection with this enterprise, Mr. Castner patented improvements in the manufacture of aluminum chloride and the furnaces used in reduction. The plant was extensive and well planned. Mr. Brindley, now manager of the sodium manufacture at Niagara Falls, was his chief of construction. In 1888 this plant was making 1,500 pounds of sodium per day, and therewith 500 pounds of aluminium, which was sold at $5 per pound. But dark days were ahead. The electrolytic processes for making aluminum were being perfected, and the very next year the competition was felt. Prices went down and down, until at last, in 1891, when it sold for 85 cents per pound, the chemical process was forced to acknowledge itself out of the race, although the sodium it used was costing only 10 cents per pound.

At this point Mr. Castner showed his mettle, and actually, by main force of his wonderful energy, saved his company from bankruptcy. With $250,000 invested in a plant which was practically useless and a capital of $500,000 at stake, he turned to find new uses for metallic sodium, and practically created the present sodium industry. He found a method of making sodium peroixde for bleaching purposes; he invented a process for making sodium cyanide from crude ferrocyanide, he exploited the use of sodium in making organic chemicals, such as antipyrin, and the manufacture of chemically pure caustic soda from the metal. With these opportunities for business, his company continued in existence as "The Aluminum Co., Ltd.," but made not a pound of aluminum, making profits on sodium alone.

At this period Mr. Castner became an electrochemist. Driven out of the aluminum business by electrolytic methods, he was quick to perceive the advantages of such processes, and he commenced experimenting on the electrolysis of fused caustic soda. Bringing to this his skill as an analytical chemist, with his experience in chemical engineering, the way was open to him for great achievements. His United States patent of May 12, 1891, describes the electrolytic process practically as it is carried on to-day, and established his pre-eminence in the sodium business more firmly than ever. The need for pure caustic soda, to use in manufacturing sodium, set him to experimenting in the electrolysis of sodium chloride, and by 1894 we had his perfected apparatus and process for the use of a movable mercury floor to a double cell the most elegant electrolytic process ever invented. (U. S. patents, Apr l 10th and October 30, 1894.) It is unnecessary here to describe that well known process. The writer saw the 200 horse-power experimental plant at Oldbury, which has since expanded into the 4,000 horse-power plant at Runcorn Point, on the Mersey, and the magnificent 6,000 horse-power plant at Niagara Falls. And we must not omit to record the integrity of the inventor, who turned his invention over to his once financially ruined company and brought them into such a position that they have made more profit from the soda and sodium business than they had ever hoped to make from the aluminum business. Such a turning of defeat into victory is seldom recorded in industrial annals, and the continued existence of his company is one of the finest monuments to the industry, skill and integrity of Mr Castner. In connection with this business, numerous patents on details of apparatus, baking of carbons, purification of the brine, etc., attest the ever active inventive genius.

It is not, however, alone as an inventor that we wish to speak of Mr Castner's abilities. He possessed the rare combination of high inventive ability, the genius of putting inventions into commercial, working form and good business instincts. He could not only devise, but he could construct, work and manage, and by his attractive personality he could win and hold friends and make his business position secure.

A disposition towards consumption made his health always precarious. The English winter drove him into exile to Florida or the Riviera. In October, 1899, he died at Saranac Lake, N. Y., at the untimely age of forty. His death has been a great loss to the art of electrochemistry, but his life-work will continue to be one of the brightest examples of how to win and to hold success that appears in the annals of that science.

## A NOTE ON THE CONDUCTIVITY OF NICKEL OXIDES

By A. L. Marsh.

[illegible] be the prevailing opinion that nickel peroxide is a conductor of electricity, and that, to render this material [illegible] in the storage battery, it must be mixed with a sufficient quantity of inert conducting material, such as flake graphite, to make the mass a conductor. Mr. Edison uses such a mixture in his new nickel-iron cell. While I have made no direct measurements of the conductivity of the oxides of nickel, it seems to me that the two experiments described below indicate that this compound cannot be classed as a non-conductor.

Hydrated nickel peroxide deposits as a rather dense, black coating on the anode when an alkaline tartrate solution of nickel is electrolyzed. This deposit does not noticeably reduce the current or prevent further deposition of peroxide on its surface. Electrodeposited conducting bodies may be built up one layer upon another, while non-conducting bodies act as porous partitions or diaphragms, through which further action takes place, and each succeeding layer of the material is set free at the surface of the metal electrode, assuming that the metal electrode is unattacked in each case.

In another experiment a cell was constructed having a layer of black oxide of nickel ($Ni_2O_3$) more than three sixteenths of an inch in thickness, surrounding a strip of nickel gauze. This oxide, which was partially hydrated, formed the active material of the positive electrode. Spongy cadmium, surrounding a strip of sheet iron, formed the negative electrode. There was no inert conducting substance mixed with the nickel oxide, yet the cell showed a very fair capacity per total weight.

I believe that electrochemically active nickel peroxide is a hydrated compound, and that the one with the proper degree of hydration is a fairly good conductor of electricity compared with lead peroxide.

But little is known of nickel peroxide. The lower oxides have, however, been better studied, and these are the ones used in the battery and from which the peroxide is formed electrochemically.

Nickel sesquioxide may be obtained in at least three different conditions, namely, anhydrous, $Ni_2O_3$; partially hydrated, $Ni_2O_3 \cdot 2H_2O$, and hydroxide, $Ni_2(OH)_6$. The second, $Ni_2O_3 \cdot 3H_2O$, is the compound which Wernicke believed to be formed during the electrolysis of an alkaline tartrate solution of nickel, but I think it more likely that nickel peroxide is at first formed and becomes reduced by a secondary action, due to the reducing medium in which it is formed.

There may be an analogy between the sesquioxide of nickel and lead peroxide as regards their conductivity with different degrees of hydration. Anhydrous lead peroxide is a very poor conductor compared with the hydrated peroxide formed at the anode during the electrolysis of a nitric acid solution of lead nitrate, so we might expect to find anhydrous nickel sequioxide a poor conductor compared with the hydrated varieties of the same compound.

Nickel sesquioxide, prepared by heating nickel nitrate, $Ni(NO_3)_2$, is anhydrous, and when this compound was used to form the peroxide electrolytically very poor results were obtained. Poor results were also obtained when the green oxide of nickel was used in the same way. In both of these cases the oxides used were not in the proper condition for rapid and efficient formation into the hydrated nickel peroxide, which I assume to be the compound of nickel of the charged electrode. In these cases an admixture of graphite might have aided the formation. Heat seems to render the oxides of nickel inert, as it does the oxides of the similar metal iron. Lead peroxides can be formed electrolytically from the lower oxide, PbO, prepared by heat, and therefore anhydrous. Heat does not affect the oxide of lead as it does the oxide of iron, for the oxide of lead is readily dissolved by nitric acid, while the oxide of iron becomes practically insoluble after being heated. Nickel being a metal somewhat similar to iron, we should expect its oxide to become less active after being heated, and this seems to be the case in regard to its behavior towards electrolytic oxidation.

Nickel hydroxide is a very bulky compound, and practically the same objections to its use in the storage battery are found as Mr. Edison has found in the use of the bulky hydroxide of iron for the negative electrode of his cell.

In my experience, the best compound of nickel to use in the storage cell is the hydrated sesquioxide, $Ni_2O_3 \cdot (H_2O)_x$, in which x represents a quantity of water less than the hydroxide contains. This compound can be peroxidized electrolytically with ease, and without the aid of inert conducting substances. In preparing this hydrated sesquioxide, I use the following method:

Nickel sulphate is dissolved in water, and by adding a strong solution of caustic soda, green nickelous hydroxide is precipitated. An excess of the caustic soda solution is added, and then a current of chlorine gas is allowed slowly to bubble through the liquid containing the nickelous hydroxide in suspension until that compound becomes jet black and all of it has been oxydized to nickelic hydroxide, $Ni_2(OH)_6$. The black hydroxide is then washed free from alkali and salts, and then spread out in the air to dry. A large shrinkage occurs in the mass, due perhaps to the loss of a part of the water of hydration. The air-dried material is ready for use in the battery.

While I do not think the flake graphite necessary to increase the conductivity of the active mass, especially when the compound is properly prepared, yet I do think that it may perform a valuable service in the positive electrode by preventing the peroxide from falling out of a perforated grid. My experience with the peroxide of nickel has shown that there is but little cohesion between the particles of oxide, even after the mass has been subjected to a considerable pressure. The particles very readily pass through the small openings of the grid, and to prevent this the flake graphite may be of some value.

From the evidence stated above, I think that nickel peroxide should not be termed a non-conductor, even from a practical standpoint, but should be classed with the conductors.

## HOW TO DETERMINE THE BEST CONDITIONS IN STORAGE-BATTERY PRACTICE.

By Carl Hering.

In expressing opinions on a storage battery, there are two extremes to which those judging them are likely to go. On the one hand the so-called scientist or theorist, who too often has an unwarranted contempt for matters involving dollars and cents, is apt to lay great stress on such qualities as the efficiency, the internal resistance, the voltage, drop in voltage, etc., ignoring completely the purely commercial considerations.

On the other hand the so-called practical or "self-made" man, who has often not had a proper training in the principles and laws involved, and too often has an unwarranted contempt for what he calls mere theories, generally meaning thereby a good scientific education and ability to make calculations, will be apt to fail to notice serious and often fatal defects in a battery, which, though perhaps not evident at first, are certain to develop later.

When any piece of scientific apparatus, as the original storage battery was, is to be used industrially, it is just as important to consider the questions of dollars and cents as the purely scientific features. The proper way to judge a battery as a commercial article is to give proper weight to both.

Dynamos and motors might, perhaps, be built with as high an efficiency as 99 per cent., but every well-trained electrical engineer knows that they would then become so expensive that no one would buy them. They would be a scientific success,

but a commercial failure. On the other hand, very cheap ones could be built of very low efficiency, but a person who can calculate in advance will often find that this continual loss of power will in the course of time amount to more in cost than the original difference in price. There is always a proper mean between these two extremes, and it is the duty of the trained engineer to determine this.

As this is well understood among those who make, sell or buy dynamos and motors, it is strange to see that the same reasoning is not more generally applied to storage batteries. One reason, undoubtedly, is that the corresponding calculations are not quite so simple, and the required data are not always at hand. But this does not excuse ignoring these questions completely.

A very similar case is found in the determination of the most economical use of incandescent lamps, which is also somewhat complicated, and although the author called attention to a method nearly ten years ago, and showed* how the conditions of the lowest cost in their use may be determined, it was not until recently that the principles involved were begun to be recognized.

As the conditions are in some respects somewhat similar in determining the most economical use and construction of incandescent lamps, and the most economical use and construction of storage batteries, and as the former method may not yet be generally understood, it may be briefly described here to facilitate the understanding of the latter.

A lamp may be made to have a long life, and the cost of the lamp itself per hour of its life will therefore be small. The efficiency, however, will then be poor and the cost of the current per candle power hour will be relatively high. On the other hand the lamp may be made to have a high efficiency, but a short life, and the cost of the lamp per hour then becomes greater, while that of the current becomes less. The gradual deterioration by blackening of the globe and the reduction in efficiency may be included in the above by using a candle power hour as the unit instead of the lamp hour.

Now the total cost to the user is, of course, the sum of these two; it is evidently immaterial to him how this cost is divided between the two, as he is only concerned with the total. This total cost will rise by going to either of these extremes, hence there must be a minimum cost somewhere between the two, and the question is to find the conditions under which this minimum is reached. This minimum, of course, will be different for different costs of the lamps, and for different costs of the power, but the method of determining it is the same for all.

The way to do this is to plot two curves, one of which shows for each successive hour in the life of a lamp, the total quantity of light given off by it in candle power hours, from the time the new lamp was first started. The other curve gives for each successive hour in the life of the lamp, the total cost of this light; that is, the original cost of the lamp added to the cost of all the energy consumed by it from the time the new lamp was first started, up to the respective hour. If for each hour this total cost, at that hour, as given in the second curve, be divided by the total quantity of light delivered up to that hour, as given by the first curve, the quotient will be the average cost per candle hour from the start to that hour. When these quotients are plotted as a third curve it will be found to have a minimum point; that is, a point where this average cost will be the smallest. It will be cheapest to discard the lamp at that hour of its life even though it may not be broken or greatly blackened.

The general method of finding such a minimum is as follows. First of all, there is the specific quantity under discussion, whose minimum (or perhaps maximum) is to be found; it was the average cost of the light per candle hour in the above case; in accumulators it might be cost of the battery per kilowatt hour capacity per discharge, or the length of run of an automobile driven by it (in which case it is the maximum that is sought), or the cost of the battery per mile run of an automobile before the battery must be renewed, or the number of miles run per dollar of cost of battery, or the cost of a kilowatt hour of the energy delivered, etc.; with batteries there are a number of such quantities. This quantity is usually made the ordinate, that is, the vertical scale of the final curve; it will, of course, always be different from either of the vertical scales of the two original curves, as will appear later.

The next step is to be reasonably sure that a minimum (or maximum) value can be expected. For instance, the first cost of a lead battery per kilowatt hour capacity will (in general) go on increasing indefinitely when the weight is increased and will never have a minimum, its least value will be when the weight is nothing, which in practice simply means the lighter the cheaper. The general rule to find in advance whether there is likely to be a minimum is to see whether the quantity under consideration will *increase* when one goes to both of two opposite extremes, if so, there must be a minimum somewhere between them. For instance, if one continues to decrease the weight of a battery, its life will be shortened and the cost of renewing the battery will increase the total cost per kilowatt hour capacity; on the other hand, to make it extremely heavy will increase the life, but again increase the total cost as the original cost will then be high; there is, therefore, a minimum somewhere between these two extremes.

The next step is to select the other ordinate of the curve; that is, the quantity or units in terms of which the time or condition of the occurrence of this minimum is expressed. In other words, it is some convenient quantity or scale which shows *when* this minimum is reached, while the other one shows *what* or *how much* this minimum is. In the case of the lamp it was the time in hours, and it showed at what hour the cost was a minimum. There may often be some latitude in the selection of this quantity as it enters into the question only as a sort of a scale to show when the minimum is reached. With storage batteries it might be the weight, the life, the number of cells, etc. The only conditions in its selection are that it must not, of course, be the quantity whose minimum is to be determined, and it must be the same for all the three curves, that is, for the two original curves and for the final curve. For the latter reason its selection will be governed largely by the data at hand, or which can be acquired. This quantity is usually made the abscissa, that is, the horizontal scale of the curve.

Having thus selected the two final scales to be used, the next step is to plot from known data the two (or perhaps more) original curves from which the final one is to be determined either by the addition, subtraction, multiplication or division of the two (or more) corresponding ordinates. This is shown best by the examples which follow.

The last step is to calculate and plot the final and desired curve from the two (or more) given original curves of data, the nature of the calculation, of course, depending upon what quantities the original and final curves express. This is best done roughly at first to find if there really is a minimum point and approximately where it is, as it may be beyond the practical limits of construction or use; after locating it approximately, calculate more accurately numerous points in the vicinity of the minimum point and draw the curve through them. The minimum value is then read off on the vertical scale, and the condition when this minimum is reached is read off on the horizontal scale. All that was said about the minimum point applies, of course, equally well to a maximum point.

Minimum and maximum points can also, of course, be readily calculated algebraically by means of the differential calculus, but this requires that the original data be given in the form of algebraic equations, and in many cases, especially

* Transactions of the American Institute of Electrical Engineers, vol 10, 1893, p. 65.

...ver the original data are all obtained from experiments and ...ften fairly accurate and often somewhat hazardous to ...determine from curves, the amount of work being often ...greater than the accuracy of the curves. Moreover, such equations are generally only approximate, and the errors thereby involved may change the location or amount of the minimum point quite appreciably. Another advantage of the graphical method with the curves, is that it is much easier to understand and safer to use, for those who are not very familiar with the differential calculus.

To illustrate the application of the above described general method of curves for determining the best conditions in storage battery practice, a few specific examples are here given in the following figures. It is to be noted, however, that the curves given are intended only to illustrate the method, and not to give actual values, for in some cases they have been exaggerated or distorted to serve their purpose better as examples of the method; moreover the original data may sometimes be so different from those indicated that there may not be a minimum at all, or it may lie beyond practical limits.

The numerical values of the divisions of the scales have been purposely omitted; the horizontal ones must, of course, be the same in all three curves of each example, and the vertical ones are generally very different in amount and always different in the thing they represent.

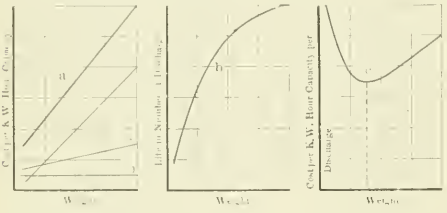

FIG. 1.—COST OF BATTERY AS FUNCTION OF WEIGHT.

The three curves of Fig. 1, show how to determine for what weight of cell the cost of the battery itself (not including the cost of the power) will be least per kilowatt hour capacity per discharge. The first two curves *a* and *b* give the original data, and the third one *c* gives the final result. The horizontal scales in all three are the weights, as that is the quantity to be used to indicate *when* the minimum point is reached. It might have been made the number of cells or perhaps some other quantity according to what one wants to take as the variable measure.

Curve *a* gives the different costs of a battery per kilowatt hour capacity when made of different weights of plates. It is made up of curve 1, which may represent the cost of forming or pasting, and will be the same for all weights, as the amount of active material is the same in all, because the capacity is assumed to be the same. Curve 2 is the cost of the jar and fixtures, which increases only slightly as the plates become thicker. Curve 3 is the cost of the lead, which increases in direct proportion to the weight. Curve 4 is the sum of these three and is the total cost, which is to be used in determining curve *c*, the subsidiary curves 1, 2 and 3 being merely given here to show how the curve *c* is itself determined.

Curve *b* gives the life in number of discharges for increasing weights; for extremely thin, light plates the number of discharges is small, it then increases as the plates are made thicker, but not as fast as the weight.

Curve *c* is the final curve desired. It is obtained by dividing, for each weight, the vertical distances or ordinates of curve *a* by the corresponding ones of curve *b*. This gives the cost per kilowatt hour of battery per discharge, and it will be seen to have a minimum value at a certain weight.

Fig. 2 shows how to determine for what weight of battery the length of the total run is greatest, for an automobile driven by it. This is a case of a maximum value. Having given an automobile of definite weight, a very light battery will run it a great distance per discharge, as there will be less dead weight of battery to carry, but the battery will have a short life, that is, it will not stand a great number of discharges, hence the total distance before the battery must be replaced, will become less. On the other hand to make it very heavy will increase the life in number of discharges, but there will be such a heavy weight to carry that the length of run for each discharge will be small. There is, therefore, probably a

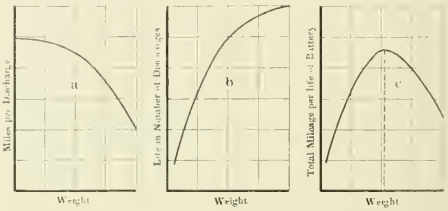

FIG. 2.—WEIGHT OF AUTOMOBILE BATTERIES.

certain weight at which there is a maximum value of the total mileage before the battery must be renewed.

The horizontal scale in all these three curves of Fig. 2, is the weight, as we want to know at what weight of battery this maximum occurs.

The first curve *a* gives the miles run per discharge, for batteries of different weights; this is great for a light battery and becomes less as the weight is increased. Curve *b* gives the life in number of discharges before the battery must be replaced by a new one; this is small for a light, short-lived battery, and becomes longer as the battery is made heavier. Multiplying each ordinate or vertical distance of curve *a* by the corresponding one of curve *b*, evidently gives the total length of all the runs that a battery will stand before it will give out. This gives curve *c*, which is the one desired and which shows that for a certain weight the total distance becomes greatest.

Had the horizontal scales been made cost, the result would have shown at what cost of battery this total run would be greatest.

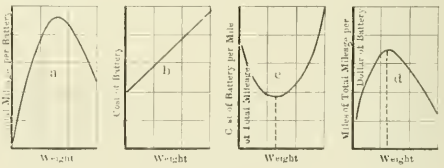

FIG. 3.—COST OF AUTOMOBILE BATTERIES AS FUNCTION OF WEIGHT.

The first three curves of Fig. 3 show how to determine at what weight of an automobile battery, the cost of the battery per mile of its total life, is a minimum. Curve *a* shows the total mileage per battery during its life; it is the same as the final curve *c* of the example in Fig. 2, thus showing how one can go from one curve to others, as in the present example this curve is used as original data. The second curve *b*, gives the cost of the battery when made of different weights. The third curve *c* is obtained by dividing the ordinates of the second curve *b*, by those of the first *a*, and it therefore shows at what weight of battery the cost of the battery is least per mile of its whole life, which are the conditions sought.

Instead of obtaining the minimum curve *c* by dividing *b* by *a*, a maximum curve may be obtained by dividing *a* by *b*; this is shown in curve *d*, which then shows at what weight the total mileage is greatest for the whole life of a battery and per dollar cost of the battery. Curve *d* is evidently only the recip-

rocal of curve *c*, and it is a mere matter of choice between them, as the ultimate result is the same in both.

The three curves of Fig. 4 show how to find at what age in its life is the average cost of one kilowatt hour of energy given out by it, a minimum. It takes into account the gradual depreciation of the capacity of the battery, and it differs from the other examples in that the curves are what are called integration curves; that is, the vertical distances represent totals, or the summing up of all the previous costs or amounts of energy up to that point, and therefore one can, from such values, find what the *average* value has been up to any particular age of its life. This case is quite similar to the one above described concerning the best age of incandescent lamps.

FIG. 4.—AVERAGE COST OF ENERGY OF A BATTERY.

It is here assumed that as the battery gradually depreciates, the amount of energy given out by it per discharge becomes less and less, although the amount put into it is the same. During the first part of its life the average of the total cost of both energy and battery will be great, because the first cost of the battery itself distributed over comparatively few discharges will be relatively great. On the other hand, if the battery is used for very many discharges its first cost per total kilowatt hours delivered will become very small, because the total number of kilowatt hours delivered by it during the many repeated discharges is very great. But owing to the depreciation of the capacity, the cost of the power delivered by it becomes greater because the capacity is reduced, although the power for charging it remains the same; therefore the average of the total cost of a kilowatt hour of energy delivered, including both the cost of power and battery, will be least at some age between these two extremes.

The horizontal scales in all of them represent the age or life stated in number of discharges. Curve *a* gives the *total* costs paid out up to the end of each discharge; it is made up of several subsidiary curves 1, 2 and 3. Curve 1 is the original cost of the battery, which, having once been paid, is therefore the same for every ordinate. Curve 2 represents the depreciation in the cost of the battery; it is here shown as based on a certain sum of money which must be charged or laid aside at every discharge, so that at the end of the life of the battery it equals the amount necessary to renew the worn out parts; but as has already been described it is a summation curve, each value of which is the *total sum* which has thus been laid aside from the beginning up to that particular discharge. This curve 2 is moreover drawn above curve 1, instead of beginning at the origin as it should if it were by itself, as the ordinate of the two curves are hereby added, and the ordinates of curve 2, in the way it is drawn, then really are the ordinates of curve 1 added to the depreciation. The distances between curves 2 and 3 represent the total cost of the power given out in the successive discharges, and as has already been stated, this increases because the amount put into the battery is the same, but the discharges grow less and less owing to the depreciation of the capacity. As before, these values represent the cost of the total power from the start and not simply for each discharge. These three curves having been drawn over each other, the last one, No. 3, at once represents the sum of all three. It should be remembered, however, that each ordinate of the last curve 3 represents the sum of all the previous costs up to that discharge, thus giving the *total* cost of the battery, the cost of all the depreciation, and of the total energy in all the previous discharges. This summation may be made for every discharge or for every 10 discharges, or in fact for any convenient period, provided only that the period is always the same; the curve is, therefore, really a step by step line, but the steps are supposed to be so frequent that the curve becomes rounded off. Such curves in which all the previous costs are added together up to each discharge, usually rise very rapidly, hence the units of the vertical scale are usually made small, so as to shorten the height of the curve.

Curve *b* simply gives the useful kilowatt hours given out by the battery up to the end of each discharge of its life; here, again, each ordinate is the sum of all the outputs of the battery in all the preceding discharges, that is, it is the total output of the battery from the start up to the end of that discharge.

Curve *c*, which is the ultimate one desired, is obtained by dividing the ordinates of curve *a* by the corresponding ones of curve *b*. By thus dividing the total money paid out up to the end of each discharge, by the total useful energy received from the start up to the end of that discharge, the result will be the *average* cost per useful kilowatt hour delivered between the start and that discharge. This average is at first quite large on account of the first cost of the battery, it then diminishes, but later on rises again on account of the great waste of energy toward the end of the life; hence it has a minimum value at a certain life, as shown by this curve. At that age it is cheaper to renew the battery than to continue to use it, even though it may not seem to be worn out.

When the final curve is relatively flat at and near the minimum point, it means that the minimum point is not sharply defined, and that one may safely go some distance to one side or the other of the theoretical point without affecting the result materially. But if the curve at the minimum point is sharp and pointed, it means that it is sharply defined, and that one should approach the exact point as closely as possible.

As has already been stated, all these curves are intended only to show in a general way how such determinations can be made, they are not intended to give any absolute values. The curves will naturally vary quite greatly with different batteries, and those of Fig. 4 will vary with different costs of the power, and when actual figures are used the minimum point may fall outside of practical limits. For instance, in the last case, Fig. 4, curve *c*, the minimum point might occur at a later time than the natural life of the battery, and it would therefore be impossible to reach this point. But even then the calculation has a value, as it shows conclusively that the life of the battery is shorter than that required to give the best result. If, on the other hand, the minimum point occurs much earlier than the natural life, it shows that the battery has an unnecessarily long life and it would be cheaper to force it, or to make it lighter. In this way such calculations as those here described may often lead one to approach, or even arrive at, the very best conditions of operation or construction.

## CALCIUM CARBIDE AND ACETYLENE.

Calcium carbide, $CaC_2$, was prepared by a purely chemical method in 1862 by Wöhler, who heated an alloy of zinc and calcium with an excess of carbon. The great calcium carbide industry of the present time, however, depends upon the electric furnace process. Calcium carbide was produced in a small way by the Cowles brothers in their electric furnace while it was used in Cleveland. The production on a commercial scale in the United States dates from 1894, when Thomas L. Willson developed the process in Spray, N. C. Since that time the calcium carbide industry has made enormous progress, which was even too rapid in various countries to be sound, and at present it is one of the most important electrochemical industries.

The principal point which decides the economical problem of

... acetylene industry ... to find well-paying ... and application for calcium carbide. The use of calcium carbide as a reducing agent for various metallurgical processes has attracted considerable attention in recent years. This interesting subject shall be dealt with in a separate article in this Journal in the near future. The main use of calcium carbide is, of course, at present the production of acetylene, and the most important problem of the calcium carbide industry is, therefore, at present most intimately connected with the problem of finding new uses for acetylene gas and to extend further the commercial use of acetylene lighting.

We will begin with a very brief review of the chemistry of the subject. Calcium carbide is prepared by heating in the electric furnace a mixture of lime, CaO, and coke. At the high temperature of the furnace, the calcium, which is formed by the action of carbon on lime, unites with carbon and forms calcium carbide, $CaC_2$. Acetylene, $C_2H_2$, is made by decomposing calcium carbide with water, according to the equation

$$CaC_2 + 2H_2O = Ca(OH)_2 + C_2H_2.$$

The combustion of acetylene gas takes place according to the equation

$$2C_2H_2 + 5O_2 = 4CO_2 + 2H_2O.$$

This last equation represents, however, the total combustion process. According to this equation, the combustion would be

WORKS OF UNION CARBIDE CO., NIAGARA FALLS.

bimolecular, while it has been pointed out that chemical processes are almost always mono- or bimolecular, and that in such cases in which a reaction is represented by an equation indicating several molecules it is probable that several intermediate reactions are involved.* Indeed, from a kinetic standpoint, polymolecular reactions should be expected to be rare, because there is only a slight probability of a large number of molecules coming together in just such a way that the reaction can take place. A reaction is much more likely to proceed in a way which involves the interaction of only very few molecules. This has, indeed, been found to be the case with our reaction, as Bone and Cain proved that there are different steps, the first of which is represented by the bimolecular equation

$$C_2H_2 + O_2 = 2CO + H_2.$$

Finally CO and $H_2$ then burn further to $CO_2$ and $H_2O$.

While the calcium carbide and acetylene industries are closely connected, and depend the one upon the other, they are not connected financially, both industries being operated separately and backed by separate capital.

The electric furnace process of making calcium carbide, as worked by T. L. Willson in 1894, was discontinuous. One of the most important improvements in the development of this industry was accomplished by Charles S. Bradley, who made the process continuous. A general outline of the process, as it is worked at present by the Union Carbide Co. at Niagara Falls, was given by J. W. Richards in ELECTROCHEMICAL INDUSTRY, Vol. I, page 22. A large amount of the power of the new water-power plant at Sault Ste. Marie has been contracted for by the same company for the purpose of making calcium carbide. We hope to publish a detailed article on the technical problems in the calcium carbide manufacture in the near future.

Concerning the theoretical yield of carbide furnaces, a number of calculations have been made, which are especially interesting in one point, as they show how different results are obtained in such calculations of the theoretical yield, on account of the uncertainty of the assumptions made. J. B. C. Kershaw has given an interesting summary of the results obtained by nine different authors. The kilowatt hours theoretically necessary to produce one metric ton (2,200 pounds) of calcium carbide, containing 80 per cent. carbide, vary between 1,523 and 3,293 (London *Electrician*, November 23, 1900, pages 164 and 245). The same author also gives figures from actual practice. These figures still vary considerably, but he believes that the most reliable figures for the kilowatt hours necessary to produce one metric ton of calcium carbide, containing 80 per cent. of carbide, is between 3,800 and 4,100 kilowatt hours.

While the calcium carbide industry in the United States is in the hands of a single company, and is developing along steady and conservative lines, the development in Europe, especially on the Continent, was characterized by the sudden erection of a great many plants, with a resulting enormous overproduction. The crisis which then set in was inevitable. Many European calcium carbide plants either stopped operation entirely or undertook the production of other electrochemical products more profitable under the existing conditions. It is estimated that on the European continent, allowing a reasonable rate of increase in the consumption of acetylene, it will probably require ten years before the demand for calcium carbide equals the present manufacturing capacity (*Mineral Industry*, vol. 10, p. 74).

Some remarks on page 453 of volume 8 of the *Jahrbuch der Elektrochemie*, which has just been issued, are very interesting in this connection. It is pointed out that the insufficient demand cannot be considered to be the only reason of the industrial European crisis, but that an important point is the fact that it is not at all easy and cheap to make calcium carbide of the good quality required for acetylene manufacture, especially if the raw materials are not pure.

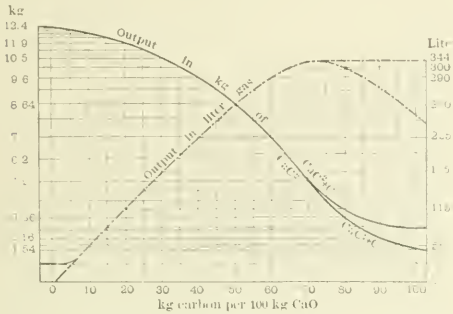
*Mineral Industry* (vol. 10, p. 75) sets forth some important points in this connection, explaining the better condition of the American industry. In Europe the prevailing custom is to remove calcium carbide from the furnaces by the so-called "tapping" process, while in America the ingots are taken directly from the furnace. It is now conceded that a more uniform quality can be produced by the latter method, and the greater purity of the raw materials in America yields a higher grade of calcium carbide than that generally produced in Europe.

An interesting investigation of the relations between the output of calcium carbide and of acetylene under different conditions of manufacture was made by Keller, of the Compagnie Electro-Thermique Keller, Leleux et Cie, in Paris. Its results were presented to the Third International Acetylene Congress in Paris, and may be seen from the adjoining diagram.

In the plants at Meran and Milan, the average current used in the furnaces was 7,500 ampères at 30 volts. The left-hand scale of the diagram gives the number of kilograms of carbide per 24 kilowatt hours; the right-hand scale gives the number of liters acetylene gas (at 760 mm. pressure and 15° C.) per kilogram of "carbide" obtained in that case. The scale of the axis of abscissas gives the number of kilograms of carbon per 100 kilograms of lime put into the furnace. If the mixture used in the furnace consists of 100 kilograms CaO and 65 kilograms C, an output of 6.2 kilograms calcium carbide per kilowatt day and a development of 300 liters acetylene per kilogram

* Holleman Inorganic Chemistry (Cooper) p. 152 and 239.

carbide were obtained. If a mixture of 100 kilograms CaO and 60 kilograms C is used, an output of 7 kilograms CaO per kilowatt day and a development of 200 liters acetylene per kilogram carbide were obtained. This shows that 1 kilowatt day yields in the first case 1,850, and in the second case 2,030 liters of acetylene.



OUTPUT OF CALCIUM CARBIDE AND ACETYLENE.

As we said before, the future of the calcium carbide industry is intimately connected with the future of the acetylene industry, and it is a very favorable symptom that both industries show at present in this country a steady and healthful growth and progress. True, the use of acetylene for power purposes may still be said to be in an experimental stage, and it is doubtful whether the acetylene motor will ever find a very extended use for general power purposes, but the use of acetylene as an illuminant is extending steadily and on a sound basis. This was not always so.

From the beginning, many would-be inventors were attracted by the apparently very simple problem of generating acetylene gas by bringing calcium carbide and water together. The list of acetylene apparatuses patented in Washington numbers about 1,000. It was overlooked that the problem of acetylene lighting must be considered with due regard to the chemical principles of the combustion of inflamable gases.

In the last years the problems involved in acetylene lighting were carefully studied, and the main principles are now well understood, with the result that reliable and safe apparatuses are now on the market. And it seems safe to conclude that, under these conditions, and on account of the excellence of the acetylene light itself, its use will increase steadily and rapidly, especially for certain purposes and in certain parts of the country. The fine display made by the acetylene interests at the Buffalo Exposition has largely contributed to the present growth of the acetylene industry.

## THE STORAGE BATTERY AS AN ELECTROLYTIC CELL.

BY C. J. REED.

All galvanic batteries, whether secondary or primary, are electrolytic cells, although electrolytic cells are not all galvanic batteries.

In order to understand thoroughly the relation of primary and secondary batteries to other electrolytic cells, we must first have a clear conception of the nature of an electrolytic cell, or electrochemical system, as it should more properly be called. We must understand the fundamental process of electrolysis, which is alike in all such systems, and which forms the basis for a definition of electrochemical action.

It may seem superfluous at this late date to revert to such elementary and fundamental principles, but there appears to be a surprising lack of clear conceptions on this subject, even among those who are supposed to know it thoroughly.

A short time ago a certain professor of physics in a well-known university made the statement, in the presence of the writer, that the *slightest external electromotive force* is sufficient to send a current in either direction through any electrolytic cell. On being asked whether this statement applied to an electrolytic cell consisting of an electrolyte of sulphuric acid, a cathode of lead and an anode of lead peroxide, he replied: "Oh, that is a storage battery." This answer showed that, in his opinion, a storage battery was not included in the category of electrolytic cells. His conception of an electrolytic cell was probably limited to an *electroplating* cell.

Conceptions of this kind are our stumbling blocks, and are the source of innumerable, unnecessary hypotheses and assumptions, invented for the purpose of explaining imaginary inconsistencies in nature.

There is no distinction to be made between electrochemical and electrolytic action. Both of these terms define the same fundamental process, which is perfectly distinct from all other processes in nature, and is the characteristic of all primary and secondary galvanic (voltaic) and other electrolytic cells. Not only is this process perfectly definable in terms applicable to all cases, but the mechanism required for its operation is definitely and universally the same.

This fundamental characteristic of electrochemical action is *change of chemical valence or combining capacity* in a particular manner. This change is always produced whenever an electric current passes from an electrode to an electrolyte, or from an electrolyte to an electrode. The change of valence is always in a specific direction at the cathode, and is always of the same quantity and in the opposite direction at the anode; but is never in both directions at the same place. At the cathode the change of valence always tends to liberate an electropositive body from combination, and always tends to cause an electronegative body to enter into combination. At the anode the change of valence always tends to liberate an electronegative body from combination, and always tends to cause an electropositive body to enter into combination. This is the distinguishing characteristic of all electrolytic or electrochemical action, and the only one.

There are other results which generally accompany the passage of an electric current through an electrolytic cell, but they are not characteristic. For example, a particular substance is generally transported through the electrolyte in a particular direction with reference to the current as a result either of the chemical changes or of the current, but this is not always so. Lead, thallium, sulphur, nitrogen, silver, gold, manganese, and many other substances are sometimes transported during electrolysis to the cathode, sometimes to the anode, and some of these substances may be transported towards both electrodes simultaneously. There is no other universal change or effect produced by or in electrochemical action, except the characteristic changes in valence above referred to, which is available for defining electrolysis.

Changes in chemical valence are of frequent occurrence in ordinary thermochemical reactions, but in these cases the opposite changes in valence occur in two atoms or atomic groups which are in intimate molecular contact with each other, while in all electrochemical reactions the atoms undergoing opposite changes of valence are never in contact with each other, but are always at the terminals of a body of electrolyte which intervenes between them, and in which there is no change of valence. Whenever there is a change of valence in any chemical reaction, thermochemical or electrochemical, it is always of the two kinds above mentioned. There never can be an increase of electropositive valence without an equal simultaneous increase in electronegative or decrease in electropositive valence. Nor is there ever a increase in electropositive valence without an equal simultaneous decrease in electronegative or increase in electropositive valence. The essential and universal difference between thermochemical and electrochemical reactions is that, in thermochemical reactions, these two oppo-

changes of valence take place in two individual atoms or atomic groups which are at the same place and in contact, the energy change being from chemical energy to heat and from heat to chemical energy; while in electrochemical reactions the two opposite changes of valence take place in atoms or molecules which are not in molecular contact, but are physically separated by an intervening compound conducting body, which undergoes no change of valence, the energy change being from chemical energy to electrical or from electrical into chemical energy.

Having accepted this conception of the nature of an electrolytic cell we are prepared to consider the relation between storage batteries and other electrolytic cells.

The difference between galvanic batteries (whether primary or secondary) and other electrolytic cells is entirely one of energy. In the nature of the electrolytic process there is no difference whatever.

In every chemical change there is always a transformation of energy. Either chemical energy is converted into another form or some other form of energy is converted into chemical. There are chemical changes in which no changes of valence occur, but we are not particularly concerned with changes of this character. They are called reactions of double decomposition, and the energy transformed in reactions of that kind is always comparatively small. In chemical reactions resulting in changes of valence, there is generally a transformation of a large amount of energy. In all chemical changes the transformation of energy must take place where the change in matter occurs. In a thermochemical reaction the transformation of this energy must all occur at the single point where the two reacting molecules or atoms undergoing the change of valence are brought in contact. In electrochemical reactions the transformation of energy corresponding to any change of valence must also occur at the point where the matter undergoing the change is located. We have seen that in electrochemical changes the changes in matter must necessarily occur at *two* different points. Hence, in an electrochemical action the transformation of energy must always occur at two different points, namely, at the terminals of the electrolyte; that is, at the two junctions of the electrolyte with the electrodes, where the corresponding changes in matter occur. The quantity of energy transformed at each of these two points will, in all cases, depend upon the nature of the substance undergoing a change of valence and the energy corresponding to such change. In such changes the energy transformed, or at least a great part of it, will always be in the form of electrical energy, either before or after the transformation; whereas in thermo-chemical reactions it will always be in the form of radient energy (heat or light).

In the electrochemical reaction, however, the electrical energy, if it appears after the transformation, may be immediately converted into heat by bringing the electrodes electrically to the same point; that is, by connecting them with an electrical conductor of low resistance, or by short circuiting the cell. In this case the energy (heat) is evolved not only at the two electrolytic junctions, but throughout the entire system, as it would be in a thermo chemical reaction, with the reacting components uniformly distributed.

The current strength is always the same at both electrodes of an electrochemical cell, and therefore an electromotive force must always be either developed or absolved at each electrode proportional to the transformation of chemical into electrical or of electrical into chemical energy at that electrode.

It follows from the above statements that, in any electrolytic cell, there is always developed at an electrode an electromotive force tending to increase the current, if chemical energy is changing into electrical energy at that electrode; that is, if the change of valence diminishes or dissipates chemical energy, and an electromotive force opposed to the current if electrical energy is changing into chemical energy; that is, if the change of valence at the electrode increases or accumulates chemical energy.

It is evident that electrical energy may be evolved at one electrode of an electrolytic cell and simultaneously absorbed at the other; that it may be evolved at both electrodes simultaneously or absorbed at both electrodes simultaneously, and it is further evident that the quantities of energy evolved or absorbed at the two electrodes may be equal or unequal, depending upon the nature of the substances concerned in the reaction.

Remembering that whenever electrical energy is evolved, chemical energy disappears, and whenever electrical energy is absorbed, chemical energy is generated, we see that, if the sum of the changes at the two electrodes evolves electrical energy, the cell or system as a whole is acting as a source of electrical energy, or it is a galvanic battery in the process of discharging. If the sum of the changes at the electrodes absorbs electrical energy, the system is acting as an accumulator or generator of chemical energy. If the chemical change at one electrode is equal and opposed to that of the other, as, for example, when the chemical change at one electrode is reversed at the other electrode, the cell as a whole will neither generate electrical energy nor accumulate chemical energy. Such a cell can neither oppose an electrochemical electromotive force to the passage of a current in either direction nor produce a current in either direction. A cell of this kind requires for the passage of an electric current through it, an external electromotive force sufficient only to overcome the resistance of the materials and the thermo-electromotive forces generated by the current itself. Electrolytic cells of this kind are, in common parlance, generally called simply "electrolytic cells," but have no specific name to distinguish them from batteries.

Electrolytic cells which are capable of generating electrical energy at the expense of their chemical energy have, from that circumstance, received the general name of batteries. The writer has suggested elsewhere that electrochemical systems which generate neither electrical nor chemical energy be called *agenic*.*

Every electrolytic cell which generates electrical energy when a current passes in one direction will generate chemical energy when the current passes in the opposite direction. Every cell, therefore, which acts as a battery when the current is in one direction is necessarily a generator of chemical energy when the current is in the opposite direction. Such cells the writer has described as *electrogenic* when they are generating electrical at the expense of chemical energy (discharging), and *electrothanic* when they are generating chemical at the expense of electrical energy (charging).

The question often arises as to what constitutes the difference between a primary and a secondary or storage battery. There is evidently no difference at all in the cell, but a difference only in *the manner of using* the cells and in their origin. If a battery is manufactured without the aid of an electric current, and is thrown away after its chemical energy is once dissipated, it is called a primary battery. If the cell has its chemical energy restored after discharge by passing a current in the opposite direction, it is called an accumulator or storage battery.

There is a distinction to be made, however, between accumulators and storage batteries. An apparatus may generate chemical energy without actually storing it. The fact that every galvanic battery will generate chemical energy when a current is passed through it in the direction opposed to its electromotive force does not signify that it will necessarily *store* the chemical energy thus generated. Herein lies the practical difference between a primary battery and a secondary or storage battery. There are very many cells in which this generated chemical energy is not available for the generation of electrical energy, on account of the purely accidental circum-

* "Electrochemical Action," Journal of the Franklin Institute, May June, 1901.

stance that the chemical products formed are mechanically lost in the process of generation. These accidental mechanical losses of material in certain cells or types of cells, however, do not constitute an essential feature on which a classification of electrochemical cells into reversible and non reversible should be founded. Such a classification implies that there are non-reversible electrochemical reactions, which is not true.

If any of the products of the electrochemical reaction formed in charging or discharging a battery are allowed to escape as a gas, or allowed to fall out of the electrolyte as an insoluble precipitate, or are allowed in any other manner to get out of the circuit, they cease to be a part of the electrochemical system, and, of course, cannot be available in that system for a subsequent operation.

In order to illustrate the foregoing statements by a familiar example, let us assume an electrochemical system to consist of an electrolyte of dilute sulphuric acid and electrodes of platinum. On passing a current through this system, the electrochemical changes at the electrodes will form at the cathode a hydride of platinum, and at the anode an oxide of platinum, the oxygen and hydrogen being derived from the decomposition of the electrolyte. These compounds of platinum have now become the electrodes of the system, and have replaced the original platinum electrodes, the platinum having been exhausted in the formation of these platinum compounds. This electrochemical reaction absorbs electrical and generates chemical energy, the electromotive force required being slightly more than one volt. If the circuit be now opened and the system examined, it will be found to be a source of electrical energy; in other words, a battery, the platinum hydride acting as the anode and the platinum oxide as the cathode in discharging. Its electromotive force will be approximately one volt at the beginning of discharge.

If, instead of interrupting the current when the platinum electrodes have been exhausted by conversion into compounds of platinum with oxygen and hydrogen, we allow the current to continue, an entirely different electrochemical reaction will take place. There being no more platinum to combine with either oxygen or hydrogen, and there being no other substance present at the terminals of the electrolyte capable of undergoing any chemical change under these conditions, the electrolyte itself must decompose in the easiest manner, liberating hydrogen at the cathode and oxygen, hydrogen peroxide or persulphuric acid at the anode.

The electric current, in crossing the junction between an electrode and an electrolyte, must be transmitted by the ions which undergo the electrochemical change. This is equivalent to saying, in the language of current theories, that the ions themselves must receive or give up the electric charges which constitute a current. It is evident, therefore, that these ions on being eliminated from the electrolyte, or on going into the electrolyte, must actually conduct the total current. It is a well-known fact that oxygen and hydrogen in the gaseous state are very perfect *non-conductors*. The resistance of these substances in the gaseous state under ordinary atmospheric pressure is known to be so high that they could not in that state possibly transmit the current of such a cell without opposing a resistance enormously greater than that which has been observed.

The evidence is, therefore, conclusive that these oxygen and hydrogen ions in the particular case under consideration are not rejected at the electrodes in the ordinary gaseous form, for example, as bubbles of gas. This would be impossible, since the total current would have to be transmitted by these bubbles of gas, and not by the surrounding electrolyte. We must conclude, therefore, that these ions are rejected *in solution* as dissolved gases, in which state they may act as conductors, since, owing to their low coefficients of solubility, they would be in a highly-attenuated state, in which condition they are known to be conductors. It is also reasonable to assume that these gases in solution would conduct the current independent of any attenuated state, since many other substances have been found which conduct in solution and do not conduct in the solid or gaseous state. The fact that these products of electrochemical reaction appear as bubbles of gas, and are formed in large quantities, is easily explained, since the elimination of these substances in solution by the current would soon cause supersaturation. The gases would then be spontaneously evolved in the form of bubbles, exactly as carbon dioxide or any other gas is evolved from a supersaturated solution.

In this case, in which oxygen and hydrogen are evolved, it is evident that after these gases have passed out of the solution in the form of bubbles of gas, the chemical energy stored in them cannot be used in a subsequent operation of the apparatus, unless provision is made for collecting the gases and restoring them again to the solution when needed.

This was done by Grove in his celebrated gas battery by inverting closed tubes over the platinum electrodes to collect the evolved gases and retain them in contact with the electrodes and the electrolyte surrounding the electrodes. In this particular case the chemical energy generated in forming the platinum compounds is the only energy available in the subsequent discharge. In discharging this cell, the platinum hydride and platinum oxide are the electrochemical reagents which generate electrical energy in being changed again to platinum and in forming additional molecules of water. But platinum has the property of combining spontaneously at ordinary temperatures with either oxygen or hydrogen on coming in contact with these substances. Therefore, as the platinum hydride and platinum oxide become exhausted in generating electrical energy, the residual platinum in the Grove battery immediately absorbs the surrounding gases, both that in solution adjacent to the platinum surface and that in the reservoir above the solution surrounding the platinum plate. The platinum oxide and platinum hydride are, therefore, spontaneously formed from the stored gases as the discharge proceeds, and this process continues until the gases are exhausted. The oxides and hydrides of platinum formed in this manner are formed thermochemically, however, since the platinum is an actual contact with the gas, and the energy of these combinations is lost as heat. The electrical energy obtainable from the discharge of this cell is therefore less than that required to evolve the gases by the amount of this heat. The electromotive force of the Grove battery is, on this account, only about 1.08 volts, instead of 1.47 volts.

Although every electrochemical reaction is perfectly reversible, the reversibility is not always apparent. Owing to the fact that in most electrochemical systems several reactions take place simultaneously, which are entirely independent of each other and produce different products, an electrochemical system sometimes produces a chemical reaction with the current in one direction, which does not appear to be reversed when the current is in the opposite direction. This apparent irreversibility is due in many cases to the fact that when two or more reactions take place simultaneously at the same point, the reaction which takes place more easily with the current in one direction, reverses most difficulty with the current in the opposite direction.

Another cause of this apparent irreversibility is the mechanical construction of the cell, which is not always such as to preserve the system and retain the products of one reaction in the position required for complete reversal. Another cause which sometimes prevents reversal is the action of selective chemical affinities in the products formed, which may, by secondary reaction, destroy these products.

While all electrochemical reactions are reversible this does not imply that the process or nature of the electrochemical change is of an opposite kind. The nature of the electrochemical change is always the same.

It is frequently stated that the charging of a storage battery is reversing the process of discharge. The process is exactly

the same on discharging as on charging. The only thing changed is the electrode originally peroxide becoming the anode and the anode becoming the cathode. In charging a lead accumulator, lead sulphate is changed into lead peroxide at the anode, the electropositive valence of the anode being thereby increased; and similarly the lead sulphate is reduced to metallic lead at the cathode, the electropositive valence being diminished. In discharging, the reduced electrode becomes the anode, and the lead peroxide electrode becomes the cathode. In this second process again, the electropositive valence of the lead anode is increased and the electropositive valence of the lead peroxide cathode is reduced, so that in both cases the electropositive valence of the anode is increased and the electropositive valence of the cathode is reduced. If the discharging reaction is carried to completion, the material is all converted into lead sulphate. If, from this point the reaction is continued in either the same direction or in the opposite direction, we still continue to have an increase of electropositive valence at the anode and a decrease of electropositive valence at the cathode; but, instead of the formation of lead sulphate from peroxide and metallic lead, we have the formation of peroxide and metallic lead from the sulphate, not because of any reversal of the process but because we have different materials constituting the electrochemical system. In the beginning of discharge we have a peroxide cathode and a metallic lead anode; at the end of discharge we have a lead sulphate cathode and a lead sulphate anode. If the current is continued now in either direction, we have a system in which the anode is lead sulphate and the cathode lead sulphate. With these electrodes, the current in either direction necessarily produces lead peroxide at the anode and metallic lead at the cathode. We see, therefore, that changing the direction of the current in charging and discharging is not the reversal of an electrochemical process, but must be considered merely a reversal of material used as electrodes and produced as products. In other words, it is the *matter* which undergoes changes and reversals of combination, and not the process. We cannot expect to obtain, when we subject metallic lead to a certain process, the same products as would be obtained by subjecting lead sulphate or lead peroxide to the same process. The process of electrochemical change should always be considered as the same, namely, increase of electropositive valence or decrease of electronegative valence at the anode, and increase of eletronegative valence or decrease of electropositive valence at the cathode. There is no known exception to this statement.

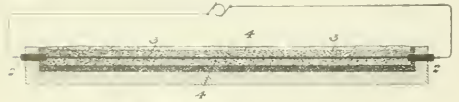
# ANALYSIS OF CURRENT ELECTROCHEMICAL PATENTS.

By George P. Scholl.

ELECTRIC FURNACES AND FURNACE PRODUCTS.

*Process of Making Graphite.* Edward G. Acheson, Niagara Falls, N. Y. Patent No. 711,031, October 14, 1902. Application filed December 22, 1900.

In this specification Mr. Acheson discloses a new method for the production of graphite from carbonaceous material. Heretofore his process consisted essentially in subjecting carbon, mixed either naturally or artificially with materials capable of forming carbides, to the intense heat of the electric furnace. A perfect transformation of amorphous carbon into graphite may however, be brought about by causing metallic vapors to act upon the amorphous carbon at the high temperature obtainable in an electric furnace. This may be accomplished by mixing metals or metallic compounds with the charge of carbon, then volatizing the metals or compounds by the intense heat, and thus causing the metallic vapors to permeate the mass of carbon. Various forms of amorphous carbon may be used and various metals or compounds employed for generating metallic vapors, such as iron, silicon, titanium, aluminium, boron or their compounds. The furnace used in the operation is shown in cross section in the adjoining Fig. 1. So-called petroleum



CHEMICAL GRAPHITE FURNACE.

coke, the residue obtained from the distillation of petroleum oil, is crushed to such a size that its particles vary in size from a powder to lumps 3 to 4 inches in diameter, and is preferably so arranged that the lumps are completely imbedded in the powder. Oxide of iron, in the proportion of 5 pounds of iron to 100 pounds of coke, is roughly mixed with the petroleum coke. The two electrodes 2, 2 are introduced through the ends of the furnace, and carbon rods 3, 3 are arranged between them to serve as preliminary conductors of the current. The entire charge 4 is preferably covered with a layer of material which does not conduct heat, such as sand and powdered carbon in proper proportion to form carbide of silicon. With a furnace 30 feet long, 14 inches wide and 18 inches deep, a current of about 200 volts and 300 ampères is suitable. As the temperature increases, this current rises quickly, on account of the reduced resistance of the carbon rods and the coke. The completion of the furnace operation is indicated by a great reduction of the resistance. During the operation the oxide of iron is reduced to metal, which either is held in the cavities or spaces between the lumps of carbon or drops to the floor of the furnace. Afterwards, as the temperature rises, the metal is volatilized, and, coming into intimate contact with the carbon, effects its conversion into graphite. After the operation the furnace is allowed to cool down, the covering of sand and carbon, which has been partially converted into silicon carbide, is removed and the coke, which has been converted into soft graphite carbon, is taken out. It is interesting to note in this connection that petroleum coke, when treated by Mr. Acheson's earlier method, was considered to graphitize very poorly (J. W. Richards, Electrochemical Industry, Vol. I, page 53). See also an article by Danneel in the *Zeit. f. Elektrochemie*, September 25, 1902, which treats about this subject, and has been abstracted in Electrochemical Industry, Vol. I, page 106.

*Object of Refractory Material and Method of Manufacturing Same.* Charles B. Jacobs, East Orange, N. J. Patent No. 711,319, October 14, 1902. Application filed December 26, 1900.

According to the inventor, who is connected with the Ampère Electrochemical Co., Niagara Falls, N. Y., this invention has for its object to provide in a commercial form bricks, tiles, blocks or other material of definite shape and of materials such as are not fusible in ordinary furnaces or ovens; for example, the silicates of aluminium and similar refractory silicates. The materials are melted in the electric furnace and cast into molds. It is stated that, in the application of the process to certain materials, such as aluminium silicate, the heat volatilizes a portion of the more volatile constituent (silica), the remaining material being less fusible, harder and tougher than the original material. Fire clay or kaolin is charged into an ordinary furnace, and an arc started between the electrodes and maintained until the mass is fused. In case kaolin or a refractory silicate is being treated, the inventor prefers to continue the heating current for a sufficient time to drive off, in the form of white clouds, a substantial percentage of the silica present in the

material. Thus the kaolin ($Al_2O_3 \cdot 2SiO_2$) is changed to the normal silicate $Al_2O_3 \cdot SiO_2$. With 200 pounds of material and a current of about 100 volts and 1,500 amperes, it takes about twenty minutes to melt the clay and about forty minutes more to drive off half the silica, so as to leave the normal silicate. This chemical change is accompanied by a very important physical change, namely, an increase of the hardness and toughness and a decrease of the fusibility of the resulting material. If the original material (fire clay) be simply fused and, without the loss of any of its silica, be allowed to cool to solid state, it will present a glossy appearance and be very brittle, but if maintained in a fused state for a sufficient time to lose a substantial or appreciable percentage of its silica, it will cool to a waxy-looking mass of an extreme degree of toughness and hardness. The molten material is poured through a tapping hole in the bottom of the furnace into metal molds. The chilling effect of the metal of the mold causes a thin crust of solidified material to be formed on the surface of the metal, and thus protects the mold from the action of the intensely-heated mass. A material like this would undoubtedly be very valuable for a good many purposes. For ordinary metallurgical uses it might, however, prove to be too expensive, as energy at the rate of 150 kilowatts per hour has to be expended in order to convert 200 pounds of material into the desired product, though the increased cost might be counterbalanced by the increased durability of the material.

*Process of Manufacturing Ferrosilicon and Silicospiegel.* Gustave Gin, Paris, France. Patent No. 712,025, November 4, 1902. Application filed April 17, 1901.

The process outlined in this specification concerns the manufacture of ferrosilicon and silicospiegel. It is proposed to use as raw material the silicon slags from metallurgical operations in the converters for the Bessemer acid process or in the Martin furnaces with silicon coatings. These slags contain, according to the specification, almost the whole of the elements which are more oxidizable than iron, and especially the metals of the alkaline earths—silicon, titanium and manganese—which existed previously in the ore or have been introduced during the process. It is stated that by regenerating these elements it is possible to obtain from by products, which are generally worthless, silicides of iron or manganese, "which enable a new cycle of refining operations to be carried on." The specification shows a number of errors in scientific terminology, such, for instance, as the continuous reference to the Martin furnaces with silicon coating, the designation of silicon, titanium and manganese as metals of the alkaline earths, the assertion that the composition of the slag of the acid Bessemer furnaces is silicate 50.82 per cent., alumina 3.15 per cent., etc. At another place it is said: "It has been proposed to extract from the blast furnaces slag carbid of calcium and cast iron, but this use is not in affinity with the particular manufacture of silicides obtained with a particular slag." It is hard to find out what particular idea is meant to be conveyed by this statement. The operation of the process itself is described as follows: "Let it be supposed that the slags to be treated come from the Martin furnaces having acid linings, and that they have the following composition: $SiO_2$, 50.42; FeO, 34.10; MnO, 0.92; $Al_2O_3$, 2.20; CaO, etc., 3.30, which may correspond per ton to the following formula: 8,400 SiO (?) + 3,800 FeO + 1,400 MnO + 220 $Al_2O_3$ + 600 CaO. I add to the slag, which has been pulverized, a quantity of carbon, so that the mixture contains one molecular proportion of carbon for each molecular proportion of oxygen in the silicate (?) and the iron and manganese peroxides without taking care of the alumina and the oxides of alkaline earths. To the slag under consideration it will therefore be necessary to add 8,400 + 2 + 3,800 + 1,400 = 22,000 atoms (?) of carbon. This can be done by introducing to the previously pulverized slag the required quantity of coal, etc. The mixture is then subjected to the heat of a continuous or alternating-current electric furnace. The most favorable voltage ranges from 25 to 30 volts and the power density (the number of volts per square centermetre of the perpendicular cross section of the electrode) should not exceed 70 volts if it be wished to reduce to its lowest practical limit the volatilization of the silicon and the manganese. Under these conditions there are not metallic carbides produced, but a bath of ferrosilicon or silicospiegel is obtained, which is run into ingot molds at intervals. In order that the operation may be carried on continuously, it will suffice to feed the electric furnace regularly with the aforesaid mixture." The derivation of the formula given above is not explained. The slag, metallurgically considered, corresponds very closely to a sesquisilicate, having a ratio of oxygen of the bases to oxygen of the silica of nearly 2 : 3. Consequently its formula would come close to $4RO, 3SiO_2$, designating by RO the monosides FeO, MnO, etc., present in the slag. Mr. Gin has had a great deal of experience in the running of electric furnaces for the manufacture of calcium carbide, and is one of the inventors of one type of them, the Gin & Leleux furnace, and the burden of proof now rests on him to show that he can produce ferrosilicon and silicospiegel economically by this process.

*Dentists' Electrical Annealing Furnace.* Nathan K. Gerhart, Indianapolis, Ind. Patent No. 712,057, October 28, 1902. Application filed August 22, 1902.

The object is to produce an efficient electric annealing furnace, particularly for the use of dentists. The heat is furnished by electric resistance coils, situated below a heating surface of isinglass or other suitable material. The articles to be heated are laid upon this surface, and are heated by radiation. Various mechanical details of the apparatus are shown, adapting the furnace specially to the use of dentists.

### APPARATUS AND PROCESSES FOR THE ELECTROLYTIC PRODUCTION OF METALS AND COMPOUNDS.

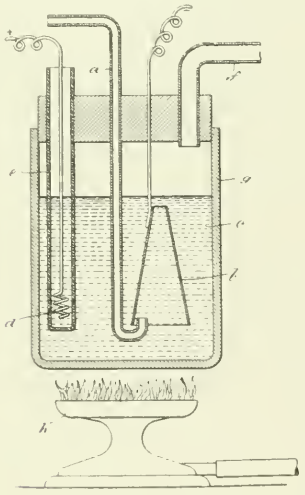
*Process of Converting Salt Marsh Material, etc., into a Fertilizer and the Product Resulting Therefrom.* J. J. Crooke, New York, N. Y. Patent No. 712,044, October 28, 1902. Application filed February 21, 1902.

The object is the conversion of the material of the so called salt marshes or salt meadows into a fertilizer. This material though it contains a great amount of humus and other compounds which would make it valuable as a fertilizer, cannot be used as such on account of certain acids, as gallic, tannic, acetic or sulphuric acids, and compounds like iron sulphide, sulphuretted and carburetted hydrogen, or an excess of chlorides, being present in it. It is proposed to subject it to electrolytic action in a wooden tank, preferably of rectangular shape, having a capacity of about 5 tons of material, and provided with an electrode at each of its sides, consisting of wrought sheet iron and arranged as a lining to the sides of the tank. The material is charged into the electrolyzer in a wet condition, and subjected to electrolysis for three to five hours. The inventor makes the remarkable statement that hydrogen is given off at the anodes, besides hydrogen sulphide, carburetted hydrogen and chlorine. The current is to be continued until the acid reaction at the anode has become neutral or alkaline. When the operation is completed, the charge is taken out, dried and pulverized, and is then ready to be used as a fertilizer. The invention is said to be applicable not only to the material from salt marshes, but also to that obtained from peat bogs, muck bogs and the dredgings of harbors, bay- and the mouths of rivers. Sheet iron anodes in the presence of chlorine will not last long, and the process seems to involve a considerable expenditure of electrical energy in comparison with the value of the finished material.

*Manufacture of Ether.* J. W. Harris, Ashboro, Pa. Patent No. 711,565, October 21, 1902. Application filed June 5, 1902.

The process relates to improvements in the manufacture of ether, which hitherto has been manufactured by mixing alcohol

with sulphuric acid, thus forming ethyl-sulphuric acid, $C_2H_5$. $HSO_4$, and then slowly adding more alcohol, which reacts with the ethyl-sulphuric acid according to the equation $C_2H_5$. $HSO_4$ + $C_2H_5$. $OH = C_2H_5$. $O$. $C_2H_5$ + $H_2SO_4$. The invention consists in the manufacture of ether directly from acetylene, thus dispensing entirely with the use of expensive alcohol. The adjoining figure shows a cross section of the apparatus in which the electrolysis is carried out. It is an ordinary cell *g*, filled with the electrolyte *c* and heated by a burner *h* to the required temperature. The cathode *b* has the shape of a cone, open at its apex, and the spiral anode *d* is surrounded by a tube or porous cell *e*. The acetylene gas enters the tube *a*, bubbles through the electrolyte and passes over the surface of the cathode *b*. The distillate passes off through the tube *f* to a second electrolytic cell, or to others if required. When passing over the cathode, the acetylene is said to combine with the nascent hydrogen liberated by the current to form ethylene and ethane, as expressed by the formula $C_2H_2 + 2H = C_2H_4$, $C_2H_4 + 2H = C_2H_6$. It is important that the production of ethane be restricted as much as possible. The electrolyte, consisting of sulphuric acid containing up to about 35 per cent. of water, is decomposed, the hydrogen acting on the acetylene and the

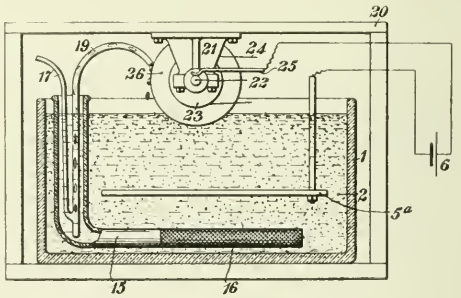


ETHER APPARATUS.

oxygen going to the anode. The ethylene formation takes place in the strong sulphuric acid, and it combines at once with the acid to form ethyl sulphuric acid, $C_2H_4 + H_2SO_4 = C_2H_5$. $HSO_4$, which combination takes place preferably at a temperature above 100° C. Water may be supplied to the cell to keep the concentration of the acid constant, or the acetylene gas may be saturated with water before entering the cell. The ethyl-sulphuric acid decomposes into products which vary with the temperature and the quantity of water present. When the water content exceeds 50 per cent., alcohol is generated. As the water content decreases, the per cent. of alcohol decreases, while that of ether begins. The alcohol formation grows less and less as the water content becomes smaller. The other formation continues until the water content is less than 10 per cent. This formation of ether is due to the reaction between two molecules of ethyl-sulphuric acid and one of water, as expressed by the equation $2C_2H_5$. $HSO_4 + H_2O = (C_2H_5)_2O + 2H_2SO_4$, the electric current assisting this to take place. It is stated that reactions forming alcohol, and subsequently ether, as expressed in the equation (1) $C_2H_5$. $HSO_4 + H_2O = C_2H_5$. $OH + H_2SO_4$, and (2) $C_2H_5$. $HSO_4 + C_2H_5$. $OH = (C_2H_5)_2O + H_2SO_4$, may also take place; but that the fact that the formation of alcohol decreases when the water content is less than 50 per cent., while the formation of the ether begins, indicates that the reaction between two molecules of ethyl-sulphuric acid and one of water is the more probable. The object of the porous diaphragm around the anode is to prevent as much as possible the oxidation of the ethyl-sulphuric acid by the oxygen liberated there. The process is an interesteing one, and if it can be carried out successfully on a commercial scale will be another step forward in the application of the electric current in the field of organic chemistry.

*Method of and Apparatus for Electrodeposition of Metals.* C. J. Reed, Philadelphia, Pa. Patent No. 712,153, October 28, 1902. Application filed August 1, 1901.

The object is to effect the uniform deposition of metals in a hard and compact form, polishing them at the same time. The apparatus is charged with a mixture of a suitable electrolyte and a granular polishing or abrading material, such as sand, for example. The cathode is arranged to be rotated, and thus comes into contact with the abrading material. One form of apparatus, intended for the electroplating of a cylinder, is shown in the adjoining figure, in which 1 is a tank or receptacle charged with the mixture 2 referred to above, and provided with an anode 5a of any suitable shape. The cathode 26 is a cylinder, mounted on a shaft 22, suspended from journals 21 and driven by pulley 23 and belt 24. It is connected by a brush



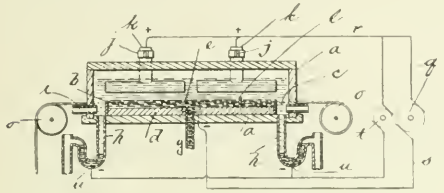
ELECTRODEPOSITION OF METALS.

25 to a suitable source of energy 6. A pipe 15, having a sieve construction 16 at its ends, is arranged on the bottom of the apparatus. Air or gas is supplied under pressure to pipe 17, thus providing effectually for the circulation of the electrolyte. Another apparatus illustrated in the specification shows the same principle applied to the simultaneous electroplating of a large number of small articles, such as tacks, buttons, articles of jewelry, etc.

*Electrolytic Cell.* A. E. Truesdell, Pittsfield, Mass. Patent No. 712,218, October 28, 1902. Application filed April 13, 1901.

The apparatus belongs to the type of mercury cells for the electrolysis of solutions of salts of the alkali metals. The cell, as shown in cross section in the adjoining diagram, consists of a slate or earthenware vessel *a*, provided with a rib *b* running parallel to each of the longer sides, thus leaving channels *c* between the sides and the side of the vessel. The mercury *e* rests on a floor *d* of cast iron. Anodes *k*, with contact pieces *j*, serve to conduct the current into the solution. For the removal of the amalgam formed by the action of the current, a sweep *l* is provided, which brushes the amalgam over the ribs *b* into the channels *a*, which slope down towards the pipes *h*, in which the amalgam accumulates. The pipe *g* serves to supply the apparatus with fresh mercury from a reservoir, in order to keep the level of the mercury at a certain height. The sweep *l* is moved by means of wires passing over pulleys *o* and introduced into the cell through stuffing boxes. It is said that the

sweep can be dispensed with, and the removal of amalgam be effected by raising the level of the mercury in the reservoir, thus forcing a certain amount of it over the ribs *b* into the channels. It is questionable whether this would have the desired effect in an apparatus large enough to be operated on a commercial scale. The main source of current is located at *g*, but, in order to prevent the discharge of amalgam in the pipes *h*, an auxiliary current is introduced, supplied from *t*, and hav-



MERCURY CATHODE CELL.

ing its minus pole connected to the amalgam at *u*. It is doubtful, however, whether a reaction of the amalgam with the solvent could be prevented, even by the introduction of a second current, if it is highly charged and stays in the pipe for some time. The admission of fresh electrolyte to the cell takes place through pipes *i*. There is nothing mentioned about the discharge of the amalgam, which evidently has to be accomplished in another apparatus. The means shown for moving the sweep, by wires passing through the electrolyte, suggest more a laboratory scale of operation than a commercial apparatus, as they probably would not last long in an electrolyte charged with chlorine, and by their solution would speedily contaminate the electrolyte.

*Electric Refining of Lead and Lead Alloys.* A. G. Betts, Lansingburg, N. Y. Patent No. 713,277, November 11, 1902. Application filed January 9, 1902.

The object is to provide a suitable electrolyte for the purpose of electrodepositing lead in a dense and coherent form. The inventor uses as electrolyte a solution proposed by him in a former patent, with the addition of one or more reducing agents. The electrolyte is an acid solution of lead fluo silicate, and among the reducing agents which he finds available are gelatine, pyrogallol, resoicinol, saligenin, orthoamito phenol, hydroquinone and sulphurous acid. Phenols of the aromatic series are said to be well adapted, by reason of their being easily oxidized. Of the above reducing agents, he has found gelatine to be the cheapest and to give the best results, and prefers to use it in the proportion of one pound of gelatine, by weight, to 5,000 parts of the solution. The gelatine is dissolved in hot water and added to the solution in the desired proportion. The presence of the reducing agent in the solution, it is said, serves to restrain the crystallization of the electrodeposited lead, and causes it to form upon the cathode in a solid body of uniform structure throughout. In this way the formation of short circuits, due to the crystallization of the electrodeposited lead, is obviated, and a product obtained which, by reason of its physical properties, facilitates the practical electrolytic refining operations, and may be fused without the formation of an undue amount of dross. The beneficent effects of the addition of the reducing agents are said to be also visible at the anode, where they preserve the mass of lead underneath the anode slime with a somewhat smoother surface. A plant for the carrying out of the process on a commercial scale, with a capacity of about 10 tons per day, is described by Ulke in the *Engineering and Mining Journal*, October 11, 1902 (see the abstract in ELECTROCHEMICAL INDUSTRY, Vol. I, page 105).

*Electrodeposited Lead.* A. G. Betts, Lansingburg, N. Y. Patent No. 713,278, November 11, 1902. Application filed October 9, 1902.

This specification is almost identical in phraseology with the preceding one, but claims the product obtained by the process described above. Claim 42 reads: "I claim ..... as a new product, electrodeposited lead characterized by substantial purity, coherency and uniformity of structure throughout, practically free from crystallization and having substantially the homogeneity, with a density of about 11.3, and retaining the normal structural characteristics due to electrolysis."

STORAGE BATTERIES.

*Accumulator.* Jean Baptiste Relin, Levallois-Perret, France. Patent No. 711,122, October 14, 1902. Application filed December 4, 1901.

The specification describes in detail the construction of a storage battery plate with the object of obtaining the maximum surface. The plates consist of a frame, usually rectangular, to which are fastened strips of lead rolled up in spiral form, having the shape of a double-spiral wood auger. The spiral slips really form the plate, as the frame serves only to support them. They are flattened down so as to form an indented strip, which is nearly flat, but provided with small projections for retaining the active material and facilitating the circulation of the electrolyte. This flattening down is performed by covering each row over with sea salt or any other substance which is hard but can be easily dissolved out. The strips are then placed in a press and partly compressed, so as to leave projections on their surface. The object of the salt is said to be threefold: to preserve the projections of the strips, to form on their surface a large number of small hollows very suitable for the formation of the active material and to clean the surface of the lead and to make it more sensible to the action of the electrolyte. After putting the plates into water, for the purpose of dissolving the salt, they are subjected to the action of a current in an electrolytic bath for their formation, or they may be filled with active material.

*Storage-Battery Plate.* N. T. Daboll, New London, Conn. Patent No. 711,481, October 21, 1902. Application filed February 10, 1902.

The object is to construct a plate of reduced weight per unit of electrical energy, and to materially reduce the operations required in forming the plate. The inventor constructs the plate out of wire gauze, coated with finely divided carbon, and then covered with white lead. The plate is a sort of flat pocket, fashioned out of iron or steel wire gauze. It is filled with finely-shredded steel, and held together by wires passed through opposite sides, in the manner of tacking a mattress. This structure is then coated with a paste, consisting of finely divided carbon made into a paste by a watery solution of any hydrocarbon—sugar, for instance—as a binder. This paste is dried, and then carbonized by the action of heat. To complete the plate, the structure is then coated with white lead and allowed to dry. This plate is certainly new, but there may be doubt about its usefulness for practical purposes.

*Storage Battery.* Frederick Sedgwick, Chicago, Ill. Patent No. 711,537, October 21, 1902. Application filed August 2, 1902.

This patent embodies another attempt at the solution of the problem of obtaining the greatest possible amount of plate surface with the least possible weight of material. The inventor builds up his electrodes from a number of exceedingly thin sheets of lead, about 2-1,000-inch in thickness. In order to provide for the circulation of the electrolyte, these sheets are first prepared by producing on them a large number of small perforations, not less than about 3,000 for each square inch of surface. These perforations are carefully distinguished from mere holes or punctures, and are made by placing the film of lead foil upon the face of a die, provided with fine longitudinal and transverse grooves, between which are projections having minute raised points. A piece of leather is then laid on the foil, and the whole subjected to pressure, thus producing in the foil a uniform series of indentations. The

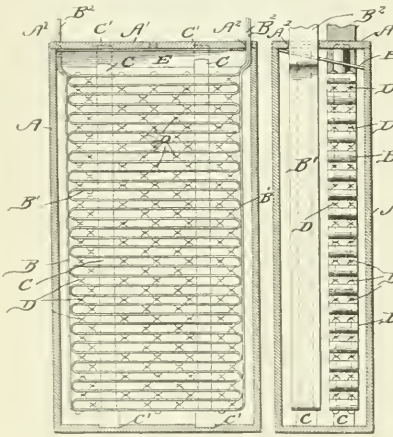
points of these pedestals are then planed or filed off, and the top thus prepared shows a regular series of minute perforations, corresponding to the raised points of the die. The surface is further roughened by means of minute grooves or indentations, and it is claimed that, when the foils are assembled, they form a wick-like cellular mass, through which a free and uniform circulation of the electrolyte may be induced by capillary attraction, allowing the gases to escape as fast as formed. The sheets or films of lead thus prepared are soldered at the top to a lead binding strip, provided with lugs for the necessary connections. Narrow strips of vulcanite or other non conducting material are inserted between the electrodes to serve as separators and prevent short-circuiting. It seems that, though the object of providing a large amount of plate surface is realized, it was attained by a more or less complicated series of operations, involving the handling of a large number of extremely thin lead foils, with its consequent practical disadvantages.

*Storage Battery.* Daniel E. Wiseman, Chicago, Ill. Patent No. 711,710, October 21, 1902. Application filed March 12, 1901.

The inventor constructs a plate consisting of one single long and narrow strip of lead, bent back and forth upon itself in serpentine form, as shown in the adjoining figure, where B' represents such a strip. The ends of each bend are soldered to that end of the strip which is intended to form the outside connection. Each strip is provided with a series of hemispherical depressions D, serving to receive the active material and at the same time to hold the bends of the strip in their respective lateral positions. Rods C, C, resting in sockets C' above and below, are provided to hold the strips in their proper position. The electrodes are arranged side by side, each consisting of one strip.

*Storage-Battery Plate.* Edward H. Winkes, Buffalo, N. Y. Patent No. 711,917, October 21, 1902. Application filed April 25, 1902.

This patent also relates to an improved form of battery plates, and embodies exactly the same idea as the preceding



STORAGE-BATTERY PLATE.

plate, in so far as a battery plate is made from a single sheet of lead bent in serpentine form, and both inventors propose to keep the folds of the plate separate by hemispherical depressions, as illustrated in the preceding patent. The main difference is that the former inventor bends a thin *strip* or ribbon into serpentine form lengthwise, whereas this one proposes to corrugate a *sheet* of lead sidewise, as it were, so closely that the corrugations are one-thirty-second to one-sixteenth of an inch apart. As the electrolyte could not directly get from one side of the plate to the other in this arrangement, a number of horizontal cuts are made in the plate, through which the circulation can take place. The inventor of the present construction provides a better support for his plates than the one of the preceding patent by mounting them in a bifurcated frame of antimonial lead and soldering the various folds to that frame. He also provides a larger number of the hemispherical depressions, intended to keep the folds separated, and, moreover, roughens the sheets before folding them, and thus furnishes a more suitable seating surface for the active material.

*Electric Accumulator.* F. Loppé, H. P. Morin, G. J. Griner and D. P. Martin, Paris, France. Patent No. 712,316, October 28, 1902. Application filed October 26, 1899.

In order to obtain a plate combining lightness with large capacity, the inventors construct the electrodes of a number of thin rectangular sheets of lead. Each of these sheets is undulated and perforated with a large number of small holes, forming conical projections, distributed over both faces of the plates. The appearance of the surface is compared to that of a nutmeg grater. A number of these sheets are arranged parallel to each other, and are then folded closely. Space is thus provided between them for the filling in with active material. The coating can either be done by pasting the active material on the sheets at the time the folds are made, or by forming them electrolytically, according to the Planté system. Separators of any insoluble substance are placed between the different electrodes of a cell.

*Secondary Battery.* Robert Welford, Sunderland, England. Patent No. 713,189, November 11, 1902. Application filed November 21, 1899.

This invention refers to the construction of a battery plate, said to be applicable to the cells of the Planté type, as well as those of the Faure type. In the case of the Faure-type cell, the inventor uses a conducting wire coiled into a helix, and surrounded by active material in such a manner that a wire constitutes the core of a rod or prism of active material. "Thus," says the inventor, "if we imagine a number of candles hanging from a horizontal rod, we obtain a good conception of an elementary form of this invention, it being borne in mind that the tallow corresponds with the paste and that the conductor, coiled or folded, corresponds with the wick." In order to keep these rods apart, a corrugated sheet of hard rubber is employed. The battery plate is constructed by laying a helix of lead wire first on one side into one of the corrugations of the hard rubber plate, then passing it underneath and up on the other side, twisting the free ends of the wire together on top of the plate. The candles of active material are now prepared by taking a quantity of paste and working it well in and behind the lead wires. If the plate is to be one of the Planté type, he uses an increased quantity of lead wire, coiled, wound or folded into more or less compact form, or places one coil of lead wire into the other. The inventor apparently did not bother about the circulation of the electrolyte.

*Storage Battery.* Bruce Ford, Philadelphia, Pa. Patent No. 712,999, November 4, 1902. Application filed August 28, 1902.

The battery plate described is provided with strips along each side, these being bent into tubular leads or flanges, which impart the requisite stiffness to the plate, and are also useful as a guide in the application of the active material. Wires may be inserted in the flanges at the corners for the purpose of strengthening them.

*Non Active Metal for Use in Storage Batteries.* H. H. Lloyd, Germantown, Pa. Patent No. 713,568, November 11, 1902. Application filed June 29, 1900.

This invention relates to a process of treating antimonial lead, containing about 12 per cent. of antimony, in such a manner that it can be made a suitable material for use in storage

batteries. Antimonial lead has heretofore been used, but the material was brittle, not flexible or resilient, and comparatively heavy in proportion to its mechanical strength, so that it could not be obtained in sheets thin enough for many purposes. The inventor claims to have discovered that such material, after having been cast, can be materially changed in its characteristics by subjecting it to repeated cold rolling or equivalent forging. The effect of the cold rolling upon the cast antimonial lead is to remove it from the class of brittle metals to the class of metals of which sheets of hard rolled copper are a good example. It is stated that the material thus prepared possesses the mechanical strength which is lacking in pure lead, resists the action of acid better than pure lead and cast antimonial lead and is much lighter than either for the same strength.

*Supporting and Lifting Mechanism for Secondary Battery Plates.* L. H. Flanders, Wilkinsburg, Pa. Patent No. 711,488, October 21, 1902. Application filed February 24, 1902.

The invention relates to means for supporting the electrodes of secondary batteries in the tanks, and for lifting the plates from the tanks for cleaning or repairs. The plates are provided on each side with a projecting lug, resting upon a bar or beam of plate glass or other insulating material, which in their turn find their support in recesses provided at each corner of the receptacle. The lifting is done by simple mechanical means.

*Separator for Storage-Battery Plates.* Rufus N. Chamberlain, Depew, N. Y. Patent No. 712,178, October 28, 1902. Application filed May 13, 1901.

The specification describes a new form of separator, which also prevents short circuits at the edges of the plates, caused by the dropping off of active material. It consists of a flat, perforated plate of hard rubber or other impervious material, which is provided with flanges along its upright edges. Each positive electrode is inclosed by a pair of separators, the side flanges of the separators inclosing the upright side edges of the electrode. The separators are further provided with spring ribs or projections, bearing against the electrodes and serving to keep the separators a little distance away from them.

*Battery Installation for Submarine Boats.* S. Lake, Bridgeport, Conn. Patent No. 712,814, November 4, 1902. Application filed March 3, 1902.

This invention has for its object to provide a storage battery installation system for submarine boats, which shall be compact, shall insure a thorough insulation between the several battery cells and their permanent relative disposition within the hull, and shall effectually prevent the escape of the battery fumes and gases into the adjacent portions of the boat. To this end, the inventor uses a special construction of air and gas-tight compartment for inclosing the system of storage battery cells, and a composite water proof insulating lining for this compartment, a water-proof and non conducting cement filling intermediate the several battery cells and the side walls. The construction is described in detail.

*Process of Forming Electric Accumulators.* W. Morrison, Chicago, Ill. Patent No. 711,997, October 28, 1902. Application filed March 18, 1901.

The specification describes an electrolytic process for the rapid disintegration of storage-battery plates, preparatory to their formation. The electrolyte proposed is hydrofluoric acid, or any of the soluble fluorides in a solution containing any of the chlorates, nitrates or similar compounds of a highly oxydizing nature capable of acting with the fluorides. Non-oxydizing agents, as acetic acid, may also be successfully used in solution with a soluble fluoride and a suitable "exciter." When the hydrofluoric acid or other soluble fluoride is placed in a solution containing nitrates, chlorates or a combination of them or similar compounds, by which fluorine gas is liberated by the action of the electric current and in combination with the other gases, the fluorine and other gases will attack the plate, producing a disintegrated material, strongly adhering to its support and throughout its mass. This material is afterward to be converted into an oxide of lead or spongy lead. If the fluorides are not used in the electrolyte, this mass will not possess the highly desirable adhesive qualities described. Special stress is laid on the assertion that nitrates, chlorates, etc., in solution with sulphuric acid, etc., do not produce sufficiently cohesive material for practical purposes. The plates to be treated are introduced into an electrolyte, as described, and used as anodes; lead plates being used as cathodes. Afterwards the plates are placed in a solution of sulphuric acid and water. It is said that, in order to hasten the process, this solution may contain zinc or any other metal capable of being deposited on the plate. This is supposed to be dissolved by the sulphuric acid and to produce nascent hydrogen, whereby spongy lead is produced on the plate. It is stated that other reducing agents, as which are named tartaric and oxalic acids, can be added to the solution in order to assist the reduction and to more completely reduce the disintegrated structure to spongy lead in a shorter time.

*Process of Peroxydizing Storage-Battery Plates.* R. N. Chamberlain, Depew, N. Y. Patent No. 712,995, November 4, 1902. Application filed August 23, 1900.

The invention refers to an improvement on the process of peroxydizing storage-battery plates. According to the inventor, the solution used up to now as an electrolyte consisted of sulphuric acid, to which a certain proportion of alkaline nitrates or a small amount of nitric acid were added. The first method is said to leave a certain amount of soluble alkaline sulphates in the bath, which are apt to lead to injurious secondary reactions; while the second method is said to have the disadvantage that the nitric acid, not being set free in the bath in a nascent state, is not as energetic as it would be if it were nascent. It is proposed to remedy these defects by adding to the sulphuric acid solution a suitable proportion of the nitrate of a metal whose sulphate is substantially insoluble in the bath—for example, nitrate of lead. The plates are first placed in a pickling solution, composed of dilute nitric acid, and are then transferred to a bath containing a solution of sulphuric acid, of 36.7 parts of $H_2SO_4$ to every 100 parts of water. To this are added 16 parts of nitrate of lead. The plates to be peroxydized are connected as anodes in this bath, preferably before the addition of the nitrate of lead. Upon electrolysis, lead nitrate is formed at the anode, which is immediately converted into sulphate, adhering to the anode. This is gradually converted by the oxygen into peroxide of lead. On addition of lead nitrate to the solution, lead sulphate is, of course, precipitated, and new nitrate of lead is added from time to time to maintain the efficiency of the bath. The precipitated sulphate which accumulates in the bath, is removed from time to time. After the plates have received a sufficient coating of peroxide, they are taken out of the bath, washed and put in the ordinary forming bath, where they are electrolyzed till all the sulphate of lead remaining on them has been cleaned off.

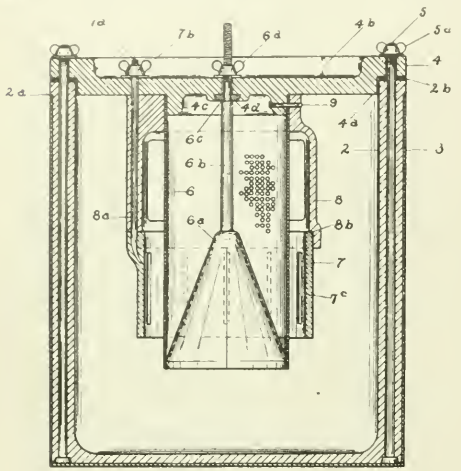
## GALVANIC CELLS.

*Gravity Battery.* W. N. Gore, Philadelphia, Pa. Patent No. 712,008, November 4, 1902. Application filed January 10, 1902.

The invention applies particularly to gravity cells like the ordinary crow-foot cell, and consists in replacing the copper electrode used in this type of cells by one composed of Babbitt metal. The inventor claims that by this substitution the strength of the battery is materially increased, and that one cell containing Babbitt metal as one of the electrodes is equal in strength to two cells in which copper is used in series. The e. m. f. of the crow foot cell is about .98 volt, and the cell under consideration is stated to have an e. m. f. of 1.2 volts. Claim No. 1 covers broadly the use of Babbitt metal as an element of any battery.

*Voltaic Cell.* Herbert B. Taylor, Newark, N. J. Patent No. 713,174. November 11, 1902. Application filed April 2, 1902.

The specification describes a new form of battery of the zinc copperoxide type, belonging to the class of water tight cells, and primarily designed for use on boats or automobiles.



ZINC-COPPEROXIDE CELL.

Its construction can be seen from the accompanying figure. Here 2 represents the jar, preferably of hard fibre, covered on the outside with a metal jacket 3. From the cover is suspended a separator or insulator 8, of the same material as the jar and cover, serving to support the positive zinc electrode. There is also suspended from the cover a so-called "container" 6, preferably of perforated metal. The bottom of the container is formed by the negative electrode 6a, of copper, in the shape of a cone, on which rests the material used as a depolarizer, small cakes or pellets of cupric oxide being preferably used in this instance. It will be seen from the figure that the cell can be quickly taken apart and repaired if necessary.

*Electric Battery.* Albert J. Cook, Jersey City, N. J. Patent No. 710,953. October 14, 1902. Application filed July 20, 1901.

The specification describes at length a new form of cell, constructed with a view of obtaining as large an electrode surface for a given space as possible, and facilitating charging and repairs. One electrode is made in one piece of rectangular cross section, and divided into four compartments, each being of triangular shape. Porous cups, also of triangular shape, are inserted into these compartments and the opposite electrodes, four in number, and also of triangular shape, are introduced into the porous cups. A system of ribs on the bottom of the containing vessel, into which the various parts fit, serve to keep them in position. The cover is made fluid-tight. The cell is evidently designed for use on automobiles.

*Tank.* Hugh Bradshaw, Chicago, Ill. Patent No. 711,465. October 21, 1902. Application filed June 13, 1902.

The invention "relates to a form of tank adapted to be sunk into the ground for the purpose of inclosing and protecting various devices from freezing." For example, in railway signaling systems it is the practice to employ batteries for operating the various devices of the system, and it is highly desirable that these batteries be protected against weather attacks, and particularly against freezing. A tank is shown in the specification, embodying several devices to prevent cold air from getting into the interior.

MISCELLANEOUS.

*Process of Framing Glass or other Materials.* H. W. Scattergood, Philadelphia, Pa. Patent No. 709,513. September 23, 1902. Application filed June 19, 1902.

The process consists in sticking the various pieces of glass, arranged in the desired design, on a sheet of thin paper, leaving uniform spaces between the respective pieces. This is then transferred to a board, a frame of wood is put around it and the spaces are filled with starch or cream of tartar, after which the whole is covered with sand to the top of the mold. Another board is then put on top, clamped to the first, and the object is reversed. The first board is then removed, the paper stripped off and the starch or other material in the spaces metallized by the application of metal powder. Another frame is then put on top of the first one; the back of the object, with the exposed metallization, is painted over with fluid wax or any other adhesive, and the whole second frame is then filled with molten wax, which will solidify and form a backing for the object during the remainder of the process. The frames are then removed, the sand cleaned off and the starch filling in the spaces taken out, thus leaving the design, with the metallized spaces between, in such shape that it can be put into the electrolytic bath. The metallization of the spaces constitutes the cathodes, upon which the metal is deposited.

## THE ELECTRICITY BUILDING OF THE UNIVERSAL EXPOSITION OF ST. LOUIS, U. S. A., 1904.

The Electricity Building of the Universal Exposition of St. Louis, 1904, is the largest ever provided, by an exposition or otherwise, for electrical exhibits and displays. It covers virtually 300,000 square feet of ground space, as against 250,000 covered by the Electricity Building at the Columbian Exposition, at Chicago, in 1893, and 75,000 by the Electricity Building at the Pan-American, at Buffalo, in 1901. It is of most graceful design and proportions, forming an elaborate pentagon, each of its five sides presenting a succession of splendid columns after the richest Corinthian order, four sides being surrounded by a balcony of rare grace and beauty. It incloses an open central circular court, surrounded by rich colonnades, which will be banked with masses of flowers and make a pleasing retreat for visitors to the building.

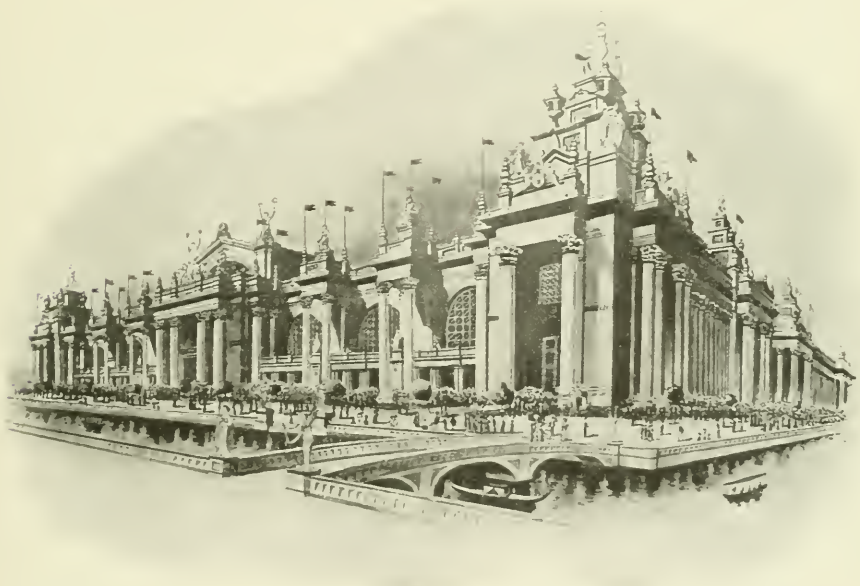
Its location within the exposition grounds is most favorable. It rises right at the foot of the grand terrace and cascades, and thus constitutes a prominent feature of the main arrangement of the rich section, which is called the main picture of the exposition. The eastern exposure of the building fronts 525 feet on the main avenue of the exposition. This broad thoroughfare leads up from the main entrance to the grand basin and cascades, and is penetrated by the central lagoon. The southern exposure, facing the grand basin and the cascades, is in direct view of the electric fountains, the peristyle of the Festival Hall and the splendid Fine Arts palaces. On the west and north the building is bordered by other principal avenues of the exposition and additional extended arms of the lagoon. It is therefore completely surrounded by water. It is led up to by splendid arch bridges, which will discharge the crowds into the broad avenues directly surrounding the building. Four main entrances are provided, one imposing portal at the meeting of the two north facades and one at the center of each of the other sides. Graceful and ample entrances are also provided at the corners of the building. The doors are of gigantic dimensions, 11 x 18 feet. The north facades of the building measure 600 feet, which makes its greater dimensions 525 x 600 feet; 176 trusses and 185 tons of steel have been used in its construction.

The details of the building are well executed in every respect. The fenestration is bold, liberal and appropriate, giving ample light, while affording substantial wall treatment. On two sides graceful and capacious loggias have been extended, which enhance the general beauty of the facades, offering pleasing

effects of light and shadow. A rare scheme of indirect illumination is being worked out, and will be applied to the building, which will accentuate its beauty at night.

The design of the building and its general and special proportions and arrangement are peculiarly adapted for an effective display of exhibits. There are numerous openings in the facades, such as exhibitors seek in selecting their exhibit spaces. Each of the 300,000 feet of floor space is directly available. It is all ground-floor space, there being not a foot of gallery space in the building, nor in any other exhibit building of the exposition, a feature of the Electricity Building and of the Universal Exposition that will be welcomed and appreciated by exhibitors and public alike.

A great traveling crane, to be used in the placing of the heavy electrical machinery which is to be exhibited, will be installed in the building, and all other conveniences afforded to exhibitors in locating and placing their exhibits.



ELECTRICITY BUILDING, SAINT LOUIS EXPOSITION.

In the Electricity Building, those electrochemical exhibits will be placed which show electrochemical processes in operation. This is in agreement with the general idea of the director of the electrical department of the exhibition, Prof. W. E. Goldsborough, to make the Electricity Building not a museum of finished products, but to make it full of life, to show how the products are made and how the processes are being worked. In this way it is hoped that the Electricity Building will become extremely attractive to the general public, who wish to see "something doing," and it is to be hoped that the electrochemical manufacturers will use this opportunity to win the interest and good-will of the general public by exhibiting model plants.

ERRATUM.—In our November issue, page 102, second column, line 13 from the bottom, there is a typographical error. The sentence should read: "Hydrogen (in combination) has always one positive bond." In the numerical applications in the same article this rule is correctly applied throughout, so that we trust our readers have already corrected the misprint.

## LOW TEMPERATURE RESEARCHES.*

BY JAMES DEWAR,

*President of the British Association for the Advancement of Science*

[*Concluded from page 91*]

The strong condensing powers of liquid hydrogen afford a simple means of producing vacua of very high tenuity. When one end of a sealed tube containing ordinary air is placed for a short time in the liquid, the contained air accumulates as a solid at the bottom, while the higher part is almost entirely deprived of particles of gas. So perfect is the vacuum thus formed that the electric discharge can be made to pass only with the greatest difficulty. Another important application of liquid air, liquid hydrogen, etc., is as analytic agents. Thus, if a gaseous mixture be cooled by means of liquid oxygen, only those constituents will be left in the gaseous state which are less condensable than oxygen. Similarly, if this gaseous residue be in its turn cooled in liquid hydrogen, a still further separation will be effected, everything that is less volatile than hydrogen being condensed to a liquid or solid. By proceeding in this fashion, it has been found possible to isolate helium from a mixture in which it is present to the extent of only one part in 1,000. By the evaporation of solid hydrogen under the air pump we can reach within 13 or 14 degrees of the zero, but there or thereabouts our progress is barred. This gap of 13 degrees might seem at first sight insignificant in comparison with the hundreds that have already been conquered. But to win one degree low down the scale is quite a different matter from doing so at higher temperatures. In fact, to annihilate these few remaining degrees would be a far greater achievement than any so far accomplished in low temperature research.

For the difficulty is two fold, having to do partly with process and partly with material. The application of the methods used

* Presidential Address, to the British Association for the Advancement of Science. On account of lack of space the chapter on the upper air and auroras, in the latter part of the address, had to be omitted. Otherwise the address is printed nearly in full.—Ed.)

in the liquefaction of gases becomes continually harder and more troublesome as the working temperature is reduced. Thus, to pass from liquid air to liquid hydrogen—a difference of 60 degrees—is, from a thermodynamic point of view, as difficult as to bridge the gap of 150 degrees that separates liquid chlorine and liquid air. By the use of a new liquid gas exceeding hydrogen in volatility to the same extent as hydrogen does nitrogen, the investigator might get to within 5 degrees of the zero. But even a second hypothetical substance, again exceeding the first one in volatility to an equal extent, would not suffice to bring him quite to the point of his ambition. That the zero will ever be reached by man is extremely improbable.

A thermometer introduced into regions outside the uttermost confines of the earth's temperature might approach the absolute zero, provided that its parts were highly transparent to all kinds of radiation, otherwise it would be affected by the radiation of the sun, and would therefore become heated. But supposing all difficulties to be overcome, and the experimenter to be able to reach within a few degrees of the zero, it is by no means certain that he would find the near approach of the death of matter sometimes pictured. Any forecast of the phenomena that would be seen must be based on the assumption that there is continuity between the processes studied at attainable temperatures and those which take place at still lower ones. Is such an assumption justified? It is true that many changes in the properties of substances have been found to vary steadily with the degree of cold to which they are exposed. But it would be rash to take for granted that the changes which have been traced in explored regions continue to the same extent and in the same direction as those which are as yet unexplored. Of such a breakdown low-temperature research has already yielded a direct proof, at least in one case. A series of experiments with pure metals showed that their electrical resistance gradually decreases as they are cooled to lower and lower temperatures, in such ratio that it appeared probable that at the zero of absolute temperature they would have no resistance at all and would become perfect conductors of electricity. This was the inference that seemed justifiable by observations taken at depths of cold which can be obtained by means of liquid air and less powerful refrigerants. But with the advent of the more powerful refrigerant, liquid hydrogen, it became necessary to revise that conclusion. A discrepancy was first observed when a platinum resistance thermometer was used to ascertain the temperature of that liquid boiling under atmospheric and reduced pressure. All known liquids, when forced to evaporate quickly, by being placed in the exhausted receiver of an air pump, undergo a reduction in temperature, but when hydrogen was treated in this way it appeared to be an exception. The resistance thermometer showed no such reduction as was expected, and it became a question whether it was the hydrogen or the thermometer that was behaving abnormally. Ultimately, by the adoption of other thermometrical appliances, the temperature of the hydrogen was proved to be lowered by exhaustion, as theory indicated. Hence, it was the platinum thermometer which had broken down. In other words, the electrical resistance of the metal employed in its construction was not, at temperatures about *minus* 250° C., decreased by cold in the same proportion as at temperatures about *minus* 200°. This being the case, there is no longer any reason to suppose that at the absolute zero platinum would become a perfect conductor of electricity; and in view of the similarity between the behavior of platinum and that of other pure metals in respect of temperature and conductivity, the presumption is that the same is true of them also. At any rate, the knowledge, that in the case of at least one property of matter we have succeeded in attaining a depth of cold sufficient to bring about unexpected change in the law expressing the variation of that property with temperature, is sufficient to show the necessity for extreme caution in extending our inferences regarding the properties of matter near the zero of temperature. Lord Kelvin evidently anticipates the possibility of more remarkable electrical properties being met with in the metals near the zero. A theoretical investigation on the relation of "electrions" and atoms has led him to suggest a hypothetical metal having the following remarkable properties: Below 1 degree absolute it is a perfect insulator of electricity; at 2 degrees it shows noticeable conductivity, and at 6 degrees it possesses high conductivity. It may safely be predicted that liquid hydrogen will be the means by which many obscure problems of physics and chemistry will ultimately be solved, so that the liquefaction of the last of the old permanent gases is as pregnant now with future consequences of great scientific moment, as was the liquefaction of chlorine in the early years of the last century.

The next step towards the absolute zero is to find another gas more volatile than hydrogen, and that we possess in the gas occurring in clevite, identified by Ramsay as helium, a gas which is widely distributed, like hydrogen, in the sun, stars and nebulæ. A specimen of this gas was subjected by Olszewski to liquid air temperatures, combined with compression and subsequent expansion, following the Cailletet method, and resulted in his being unable to discover any appearance of liquefaction, even in the form of mist. His experiments led him to infer that the boiling point of the substance is probably below 9 degrees absolute. After Lord Rayleigh had found a new source of helium in the gases which are derived from the Bath springs, and liquid hydrogen became available as a cooling agent, a specimen of helium cooled in liquid hydrogen showed the formation of fluid, but this turned out to be owing to the presence of an unknown admixture of other gases. As a matter of fact, a year before the date of this experiment I had recorded indications of the presence of unknown gases in the spectrum of helium derived from this source. When subsequently such condensable constituents were removed, the purified helium showed no signs of liquefaction, even when compressed to 80 atmospheres, while the tube containing it was surrounded with solid hydrogen. Further, on suddenly expanding, no instantaneous mist appeared. Thus helium was definitely proved to be a much more volatile substance than hydrogen, in either the liquid or solid condition. The inference to be drawn from the adiabatic expansion effected under the circumstances is that helium must have touched a temperature of from 9 to 10 degrees for a short time without showing any signs of liquefaction, and consequently that the critical point must be still lower. This would force us to anticipate that the boiling point of the liquid will be about 5 degrees absolute, or liquid helium will be four times more volatile than liquid hydrogen, just as liquid hydrogen is four times more volatile than liquid air. Although the liquefaction of the gas is a problem for the future, this does not prevent us from safely anticipating some of the properties of the fluid body. It would be twice as dense as liquid hydrogen, with a critical pressure of only 4 or 5 atmospheres. The liquid would possess a very feeble surface tension, and its compressibility and expansibility would be about four times that of liquid hydrogen, while the heat required to vaporize the molecule would be about one-fourth that of liquid hydrogen. Heating the liquid 1 degree above its boiling point would raise the pressure by 1¾ atmospheres, which is more than four times the increment for liquid hydrogen. The liquid would be only 17 times denser than its vapor, whereas liquid hydrogen is 65 times denser than the gas it gives off. Only some 3 or 4 degrees would separate the critical temperature from the boiling point and the melting point, whereas in liquid hydrogen the separation is respectively 10 and 15 degrees. As the liquid refractivities for oxygen, nitrogen and hydrogen are closely proportional to the gaseous values, and as Lord Rayleigh has shown that helium has only one-fourth the refractivity of hydrogen, although it is twice as dense, we must infer that the refractivity of liquid helium would also be about one-fourth that of liquid hydrogen. Now, hydrogen has the smallest refractivity of any known liquid, and yet liquid helium will have only about one-fourth of this value—comparable, in fact, with liquid hydrogen just below its

critical point. This means that the liquid will be quite exceptional in its optical properties, and very difficult to see. This may be the explanation of why no mist has been seen on its adiabatic expansion from the lowest temperatures. Taking all these remarkable properties of the liquid into consideration, one is afraid to predict that we are at present able to cope with the difficulties involved in its production and collection. Provided the critical point is, however, not below 8 degrees absolute, then from the knowledge of the conditions that are successful in producing a change of state in hydrogen through the use of liquid air, we may safely predict that helium can be liquefied by following similar methods. If, however, the critical point is as low as 6 degrees absolute, then it would be almost hopeless to anticipate success by adopting the process that works so well with hydrogen. The present anticipation is that the gas will succumb after being subjected to this process, only, instead of liquid air under exhaustion being used as the primary cooling agent, liquid hydrogen evaporating under similar circumstances must be employed. In this case the resulting liquid would require to be collected in a vacuum vessel, the outer walls of which are immersed in liquid hydrogen. The practical difficulties and the cost of the operation will be very great, but, on the other hand, the descent to a temperature within 5 degrees of the zero would open out new vistas of scientific inquiry, which would add immensely to our knowledge of the properties of matter. To command in our laboratories a temperature which would be equivalent to that which a comet might reach at an infinite distance from the sun would indeed be a great triumph for science. If the present Royal Institution attack on helium should fail, then we must ultimately succeed by adopting a process based on the mechanical production of cold through the performance of external work. When a turbine can be worked by compressed helium, the whole of the mechanism and circuits being kept surrounded by liquid hydrogen, then we need hardly doubt that the liquefaction will be effected. In all probability gases other than helium will be discovered of greater volatility than hydrogen. It was at the British Association meeting in 1896 that I made the first suggestion of the probable existence of an unknown element which would be found to fill up the gap between argon and helium, and this anticipation was soon taken up by others and ultimately confirmed. Later, in the Bakerian Lecture for 1901, I was led to infer that another member of the helium group might exist having the atomic weight about 2, and this would give us a gas still more volatile, with which the absolute zero might be still more nearly approached. It is to be hoped that some such element or elements may yet be isolated and identified as coronium or nebulium. If amongst the unknown gases possessing a very low critical point some have a high critical pressure, instead of a low one, which ordinary experience would lead us to anticipate, then such difficultly liquefiable gases would produce fluids having different physical properties from any of those with which we are acquainted. Again, gases may exist having smaller atomic weights and densities than hydrogen, yet all such gases must, according to our present views of the gaseous state, be capable of liquefaction before the zero of temperature is reached. The chemists of the future will find ample scope for investigation within the apparently limited range of temperature which separates solid hydrogen from the zero. Indeed, great as is the sentimental interest attached to the liquefaction of these refractory gases, the importance of the achievement lies rather in the fact that it opens out new fields of research and enormously widens the horizon of physical science, enabling the natural philosopher to study the properties and behavior of matter under entirely novel conditions. This department of inquiry is as yet only in its infancy, but speedy and extensive developments may be looked for, since within recent years several special cryogenic laboratories have been established for the prosecution of such researches, and a liquid air plant is becoming a common adjunct to the equipment of the ordinary laboratory.

VARIOUS LOW-TEMPERATURE RESEARCHES.

We may now summarize some of the results which have already been attained by low-temperature studies. In the first place, the great majority of chemical interactions are entirely suspended, but an element of such exceptional powers of combination as fluorine is still active at the temperature of liquid air. Whether solid fluorine and liquid hydrogen would interact, no one can at present say. Bodies naturally become denser, but even a highly expansive substance, like ice, does not appear to reach the density of water at the lowest temperature. This is confirmatory of the view that the particles of matter under such conditions are not packed in the closest possible way. The force of cohesion is greatly increased at low temperatures, as is shown by the additional stress required to rupture metallic wires. This fact is of interest in connection with two conflicting theories of matter. Lord Kelvin's view is that the forces that hold together the particles of bodies may be accounted for without assuming any other agency than gravitation or any other law than the Newtonian. An opposite view is that the phenomena of the aggregation of molecules depend upon the molecular vibration as a physical cause. Hence, at the zero of absolute temperature, this vibrating energy being in complete abeyance, the phenomena of cohesion should cease to exist, and matter generally be reduced to an incoherent heap of cosmic dust. This second view receives no support from experiment.

The photographic action of light is diminished at the temperature of liquid air to about 20 per cent. of its ordinary efficiency, and at the still lower temperature of liquid hydrogen only about 10 per cent. of the original sensitivity remains. At the temperature of liquid air or liquid hydrogen, a large range of organic bodies, and many inorganic ones, acquire under exposure to violet light the property of phosphorescence. Such bodies glow faintly so long as they are kept cold, but become exceedingly brilliant during the period when the temperature is rising. Even solid air is a phosphorescent body. All the alkaline earth sulphides which phosphoresce brilliantly at the ordinary temperature lose this property when cooled, to be revived on heating; but such bodies in the first instance may be stimulated through the absorption of light at the lowest temperatures. Radio-active bodies, on the other hand, like radium, which are naturally self-luminous, maintain this luminosity unimpaired at the very lowest temperatures, and are still capable of inducing phosphorescence in bodies like the platino-cyanides. Some crystals become for a time self-luminous when cooled in liquid air or hydrogen, owing to the induced electric stimulation causing discharges between the crystal molecules. This phenomenon is very pronounced with nitrate of uranium and some platino-cyanides.

In conjunction with Professor Fleming, a long series of experiments were made on the electric and magnetic properties of bodies at low temperatures. The subjects that have been under investigation may be classified as follows: "The Thermo-Electric Powers of Pure Metals," "The Magnetic Properties of Iron and Steel," "Dielectric Constants," "The Magnetic and Electric Constants of Liquid Oxygen," "Magnetic Susceptibility."

The investigations have shown that electric conductivity in pure metals varies almost inversely as the absolute temperature down to *minus* 200 degrees, but that this law is greatly affected by the presence of the most minute amount of impurity. Hence the results amount to a proof that electric resistance in pure metals is closely dependent upon the molecular or atomic motion which gives rise to temperature, and that the process by which the energy constituting what is called an electric current is dissipated essentially depends upon non homogeneity of structure and upon the absolute temperature of the material. It might be inferred that at the zero of absolute temperature resistance would vanish altogether, and all pure metals become perfect conductors of electricity. This conclusion, however, has been rendered very doubtful by

subsequent observations made at still lower temperatures, which appear to point to an ultimate finite resistance. Thus the temperature at which copper was assumed to have no resistance was *minus* 223 degrees, but that metal has been cooled to *minus* 253 degrees without getting rid of all resistance. The reduction in resistance of some of the metals at the boiling point of hydrogen is very remarkable. Thus copper has only 1 per cent., gold and platinum 3 per cent. and silver 4 per cent. of the resistance they possessed at zero C., but iron still retains 12 per cent. of its initial resistance. In the case of alloys and impure metals, cold brings about a much smaller decrease in resistivity, and in the case of carbon and insulators like gutta percha, glass, ebonite, etc., their resistivity steadily increases. The enormous increase in resistance of bismuth, when transversely magnetized and cooled, was also discovered in the course of these experiments. The study of dielectric constants at low temperatures has resulted in the discovery of some interesting facts. A fundamental deduction from Maxwell's theory is that the square of the refractive index of a body should be the same number as its dielectric constant. So far, however, from this being the case generally, the exceptions are far more numerous than the coincidences. It has been shown in the case of many substances, such as ice and glass, that an increase in the frequency of the alternating electromotive force results in a reduction of the dielectric constant to a value more consistent with Maxwell's law. By experiments upon many substances, it is shown that even a moderate increase of frequency brings the large dielectric constant to values quite near to that required by Maxwell's law. It was thus shown that low temperature has the same effect as high frequency in annulling the abnormal dielectric values. The exact measurement of the dielectric constant of liquid oxygen, as well as its magnetic permeability, combined with the optical determination of the refractive index, showed that liquid oxygen strictly obeys Maxwell's electro-optic law even at very low electric frequencies. In magnetic work the result of greatest value is the proof that magnetic susceptibility varies inversely as the absolute temperature. This shows that the magnetization of paramagnetic bodies is an affair of orientation of molecules, and it suggests that at the absolute zero all the feebly paramagnetic bodies will be strongly magnetic. The diamagnetism of bismuth was found to be increased at low temperatures. The magnetic moment of a steel magnet is temporarily increased by cooling in liquid air, but the increase seems to have reached a limit, because on further cooling to the temperature of liquid hydrogen hardly any further change was observed. The study of the thermo-electric relations of the metals at low temperatures resulted in a great extension of the well known Tait thermo-electric diagram. Tait found that the thermo-electric power of the metals could be expressed by a linear function of the absolute temperature, but at the extreme range of temperature now under consideration this law was found not to hold generally; and, further, it appeared that many abrupt electric changes take place, which originate probably from specific molecular changes occurring in the metal. The thermo-electric neutral points of certain metals, such as lead and gold, which are located about or below the boiling point of hydrogen, have been found to be a convenient means of defining specific temperatures in this exceptional part of the scale.

The effect of cold upon the life of living organisms is a matter of great intrinsic interest, as well as of wide theoretical importance. Experiment indicates that moderately high temperatures are much more fatal, at least to the lower forms of life, than are exceedingly low ones. Professor McKendrick froze for an hour at a temperature of 182° C. samples of meat, milk, etc., in sealed tubes; when these were opened, after being kept at blood heat for a few days, their contents were found to be quite putrid. More recently some more elaborate tests were carried out at the Jenner Institute of Preventive Medicine on a series of typical bacteria. These were exposed to the temperature of liquid air for twenty hours, but their vitality was not affected, their functional activities remained unimpaired, and the cultures which they yielded were normal in every respect. The same result was obtained when liquid hydrogen was substituted for air. A similar persistence of life in seeds has been demonstrated even at the lowest temperatures; they were frozen for over a hundred hours in liquid air, at the instance of Messrs. Brown and Escombe, with no other result than to affect their protoplasm with a certain inertness, from which it recovered with warmth. Subsequently commercial samples of barley, pea, vegetable marrow and mustard seeds were literally steeped for six hours in liquid hydrogen at the Royal Institution, yet when they were sown by Sir W. T. Thiselton Dyer at Kew, in the ordinary way, the proportion in which germination occurred was no less than in the other batches of the same seeds which had suffered no abnormal treatment. Bacteria are minute vegetable cells, the standard of measurement for which is the "mikron." Yet it has been found possible to completely triturate these microscopic cells when the operation is carried out at the temperature of liquid air, the cells then being frozen into hard, breakable masses. The typhoid organism has been treated in this way, and the cell plasma obtained for the purpose of studying its toxic and immunizing properties. It would hardly have been anticipated that liquid air should find such immediate application in biological research. A research by Professor Macfadyen, just concluded, has shown that many varieties of micro-organisms can be exposed to the temperature of liquid air for a period of six months without any appreciable loss of vitality, although at such a temperature the ordinary chemical processes of the cell must cease. At such a temperature the cells cannot be said to be either alive or dead, in the ordinary acceptation of these words. It is a new and hitherto unobtained condition of living matter—a third state. A final instance of the application of the above methods may be given. Certain species of bacteria during the course of their vital processes are capable of emitting light. If, however, the cells be broken up at the temperature of liquid air, and the crushed contents brought to the ordinary temperature, the luminosity function is found to have disappeared. This points to the luminosity not being due to the action of a ferment—a "Lucierase"—but as being essentially bound up with the vital processes of the cells, and dependent for its production on the intact organization of the cell. These attempts to study by frigorific methods the physiology of the cell have already yielded valuable and encouraging results, and it is to be hoped that this line of investigation will continue to be vigorously prosecuted at the Jenner Institute.

And now, to conclude my address, I may remind you that I commenced by referring to the plaint of Elizabethan science, that cold was not a natural available product. In the course of a long struggle with nature, man, by the application of intelligent and steady industry, has acquired a control over this agency which enables him to produce it at will, and with almost any degree of intensity short of a limit defined by the very nature of things. But the success in working what appears at first sight to be a quarry of research that would soon suffer exhaustion has only brought him to the threshold of new labyrinths, the entanglements of which frustrate, with a seemingly invulnerable complexity, the hopes of further progress. In a legitimate sense, all genuine scientific workers feel that they are "the inheritors of unfilled renown." The battlefields of science are the centers of a perpetual warfare, in which there is no hope of final victory, although partial conquest is ever triumphantly encouraging the continuance of the disciplined and strenuous attack on the seemingly impregnable fortress of nature.

To serve in the scientific army, to have shown some initiative and to be rewarded by the consciousness that in the eyes of his comrades he bears the accredited accolade of successful endeavor is enough to satisfy the legitimate ambition of every earnest student of nature.

## ELECTRIC PROCESS OF STEEL MANUFACTURE.

The electrometallurgy of iron and steel is at present exciting great interest. Mr. Marcus Ruthenberg's very interesting paper, read at the Niagara Falls meeting (this journal, page 84), elicited a long and animated discussion (this journal, page 58). Some information on results obtained in actual practice in Sweden and Italy were given in Mr. Carl Hering's synopsis (this journal, pages 70 and 71).

With regard to the plant in Gysinge, Sweden, a consular report of Mr. Robert S. S. Bergh, of Gothenburg, contains the following translation from a recent issue of the *Trading and Shipping Journal* of that city:

"At the meeting of the Iron Manufacturers' Association (Bruksocieteten) at Jernkontoret, Engineer F. A. Kjellin and Mr. Benedicks gave some very interesting information about the production of electro-steel at Gysinge.

"The problem of smelting steel by electricity has for a long time attracted the attention of inventors, and experiments have been made here. By the advice of Engineer Kjellin, Mr. Benedicks decided in 1899 to build at Gysinge an electric steel furnace 'without electrodes.'

"In the latter part of February, 1900, the first furnace was finished and ready for trial, and, after a few experiments, the first ingot was produced. The steel was found to be of excellent quality. The problem was thus solved technically, but not economically, for, with the dynamo of 78 kilowatts used, not more than 270 kilograms (575 pounds) of steel were obtained in twenty-four hours, and in the furnace there was not room for more than 80 kilograms (176 pounds). A larger furnace was seen to be necessary, and this was completed in November, 1900, and proved to be a great improvement. In the second furnace, which held 180 kilograms (397 pounds), from 600 to 700 kilograms (1,322 to 1,543 pounds) of steel were produced in twenty-four hours. The Gysinge sulphite factory burned down on August 11, 1901, and it was decided to build steel works in its place and to use the water power available there. For the steel furnace there was utilized a turbine of 300 horse-power, with direct-coupled generator. The new furnace is to hold 1,800 kilograms (3,970 pounds), and the production is estimated to be at least 1,500 tons a year if charged with cold raw material.

"Engineer Kjellin said that the steel produced is of superior quality and characterized by strength, density, uniformity, toughness and the ease with which it can be worked in cold, unhardened condition, even when containing a very high percentage of carbon. Compared with other steel, it also has less tendency to crack or warp when hardened.

"The reason why this steel in certain qualities differs from other steel, especially in its softness when unhardened, is considered to be its freedom from gases. The manufacture of special steel, with nickel, chrome, manganese or wolfram, will, of course, not meet with any difficulties. The chrome steel and wolfrom steel produced at Gysinge have proved to be excellent for lathe tool. When used for permanent magnets, the Gysinge wolfram steel has been found to give stronger magnets than any other wolfram steel, and has not warped in the hardening.

"From estimates made, it has been ascertained that the furnace used at Gysinge, which is simple in construction and easily managed, has prospects of competing, as to cost of operation, with the furnaces heretofore used for fusion of steel, especially as it yields steel of a better quality.

"For this country (Sweden), with its good ores and large supply of water power, the electric method of smelting steel ought to be of great importance, and abroad, where blast furnace gas is becoming a cheap source of power, it ought to come into extensive use.

"After the lecture Engineer Wahlberg made some statements concerning tests of steel ingots from Gysinge, which had been found to be uniform and homogenous. Microscopic examinations had indicated that there was no difference between the electro steel and crucible steel, which was so much more remarkable, as the electro steel in other respects had different qualities."

## REDISCOVERY OF A PROCESS FOR RENDERING PHOSPHORIC ACID AVAILABLE.

By Prof. Charles Baskerville.

In endeavoring to secure a mechanical method for concentrating phosphatic pebble, found in the coastal plain region of North Carolina (Castle Haynes Mines), the concentric structure of many of the nodules was redetermined (Penrose, U. S. Geological Survey, Bulletin 40, 77). A number of analyses of carefully selected pebbles were made, and in no case, except with the fossil teeth, which occur in the deposit to a greater or less extent, could samples be had which contained less than 15 to 20 per cent. each of silica and limestone.

The chemical methods for increasing the content of phosphate were unsuccessful from an economic point of view. Jigged material could be had, which contained from 35 to 44 per cent. of tri-calcium phosphate; so methods of fusing with substances like the alkaline, sulphates, sulphides, nitrates, and finally carbonates, were tried. The last was thoroughly successful, the nitrates giving the largest percentage of citrate soluble phosphoric acid, but the expensive nitrogen was driven off. Knoop (Bied. Centr.—B, 28,576) heated phosphates, bones, etc., with the alkaline silicates, and obtained a 99 per cent. yield of "available phosphoric acid." (U. S. patent, 691,089 (1898).

G. A. Liebig secured the American rights for a process the same as the author's, having preceded him by a few months. The process is of value in those countries where chamber acid is expensive (Sweden) and large deposits similar to the North Carolina carbonaceous and siliceous phosphates are found, as recently noted in Japan (*Science*, x, 900).

## CURRENT NOTES.

The Nobel prize for physics has been awarded to Professors Lorenz and Zeeman, the two distinguished Dutch physicists, who have taken active part in the development of the modern theory of electrons. In the subject of chemistry, the Nobel prize was awarded to Dr. Emil Fischer, who, as successor of A. W. von Hoffman, now occupies the chair of organic chemistry at the University of Berlin. Dr. J. H. van't Hoff, who occupies the chair of physical chemistry at the same university, received the Nobel prize last year. The amount of each prize is $41,600.

At the annual convention of the American Roentgen Ray Society, recently held in Chicago, Prof W. E. Goldsborough, chief of the department of electricity of the Saint Louis Exposition, made an address in which he outlined the plans of his department to bring together a thoroughly representative and advanced exhibit of Roentgen ray and electro-therapeutic apparatus. The convention passed a resolution extending assurances of its cordial support. Prof. W. E. Goldsborough also addressed the Interstate Independent Telephone Association at the recent convention in Chicago and a resolution was passed commending the Saint Louis World's Fair to the support of the independent manufacturers of telephone appliances and supplies.

The president of the Exposition Co. of the Saint Louis Exposition has just announced the organization of world's congresses, to be held in Saint Louis during 1904. Howard J. Rogers, chief of the department of education, is to be the director of congresses. The Advisory Board, to work in conjunction with him, is as follows: Chairman, Nicholas Murray Butler, president of Columbia University, New York City;

* Abstract of a paper read before the Society of Chemical Industry.

William R. Harper, president of the University of Chicago; R. H. Jesse, president of the University of Missouri; Henry S. Pritchett, president of the Massachusetts Institute of Technology, and Herbert B. Putnam, librarian of Congress. The duties of this Advisory Board will be more exacting than usually falls to the lot of advisory bodies. Upon their recommendations will be determined the number and extent of congresses, the emphasis to be placed on special features, the prominent men invited to participate, the character of the programme and the methods for successfully carrying out the enterprise. No effort will be spared to give the series of congresses at this exposition unity and connected purpose, and make their published proceedings a valuable contribution to the world's literature. A series of congresses has been an accompaniment of all recent international expositions, but they have always been disconnected and rather incident to the exposition than related to it and supplementary to the exhibits. The work of the director and Advisory Board will be wholly given to constructing a co ordinate department of the exposition, which shall have an established scientific value and attract the attention of the practical scholars and experts of the world to Saint Louis.

The Lousiana Purchase Exposition, in St. Louis, 1904, will have light effects that have not been exploited even in spectacular theatres. Chief Henry Rustin, of the electrical and mechanical department, is now conducting experiments to this end. The Nernst lamp is among those that are being tried. Other experiments are being made with the Cooper-Hewitt mercury vapor lamp, made by the Sawyer-Man Co., of New York. With this an initial pressure of between 50,000 and 75,000 volts is needed to start the light; then a pressure of only 120 volts suffices to maintain its luminosity. It is a livid phosphorescence, which imparts a ghostly pallor to objects surrounding, daylight colors being completely metamorphosed. Experiments are being made with other vapors than that of mercury, and with lamps of other patterns. It is desired to use in the cascades some phosphorescent light which will not only be luminous itself, but impart luminosity to the water it permeates. It is thought that the required agent has been found in the Geisler tube adaptation, with which experiments are now being made. These long tubes can easily be installed in the lips of the cascade ledges, and the light coming through the falling, turbulent water is expected to produce entirely unprecedented spectacular effects.

Dr. J. A. Holmes, chief of the mines and metallurgy department of the St. Louis Exposition, recently returned to St. Louis, after having been away about a month. He reports that the people of the Atlantic States now take a great deal more interest in the World's Fair than they did when he was in the East several months ago. Many of the manufacturers, who at that time were not disposed to exhibit at the fair, now announce that they desire to exhibit, and some of them have applied for space. At Pittsburg he arranged for a number of iron, steel, coal and coke exhibits, and at Philadelphia for several aluminum and iron exhibits. At New York he secured promises of exhibits illustrating different metallurgical processes in copper, lead and zinc; also exhibits in mining machinery. In Washington, D. C., he conferred with some of the Government officials in regard to exhibits illustrating ore deposits and the extent and distribution of mineral deposits in the United States. In Vermont he arranged for exhibits of slate, granite and marble.

The twenty-fifth anniversary of the Engineers' Club of Philadelphia was recently celebrated by a banquet. The guests included representatives from the national engineering societies, a large number of engineering clubs, as well as the Union League and Art Clubs of Philadelphia and the University of Pennsylvania. Among the distinguished guests were Admiral Melville and the venerable John Fritz.

# SYNOPSIS OF ARTICLES IN OTHER JOURNALS.

*A Summary of Articles on Electrochemistry and Allied Subjects Appearing in American and Foreign Periodicals.*

By Carl Hering.

## INDUSTRIAL ELECTROCHEMISTRY.

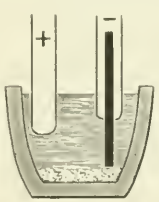
*Bleaching.*—The subject of bleaching powders and liquids is a matter which at present is becoming somewhat important, owing to the overproduction of bleaching powder as a by-product in the electrolytic alkali industry. During the past month several articles of interest in this direction have been published, one of which is on what seems to be a very simple method of producing hydrochlorite of soda for use in place of bleaching powder. The liquid must be made where it is used, but has a number of advantages which still further affect the bleaching-powder industry. The description of this cell of Walker will be found in *Eng. and Min. Jour.*, November 22d. He describes a cell devised by Atkins, of London, which consists of a semi-cylindrical wooden vat, with a horizontal axis, 10 feet long and 2 feet wide. The inside is lined with sheet lead, on which are placed carbon bricks about 2 inches thick, whose inner surfaces form a semi-cylinder concentric with the lead and wood, and act as anode; these carbon bricks are cemented together and to the lead by a water-proof carbon cement. A wooden cylinder covered with lead revolves as the cathode in the vat, within an inch of the surface of the carbons, and the solution of salt fills up the space between. The total area of the anode surface is about 20 square feet. The current used varies from 1,000 to 1,500 ampères at from 3 to 4 volts, and the amount of 10 per cent. solution of salt acted on varies from 500 to 1,000 gallons per hour, according to the strength of the resulting solution of hypochlorite that is required. While hydrogen is given off at the revolving cathode, the solution consists finally of NaClO and some unaffected salt. Owing to the great surface of the electrodes, there is very little resistance, so that the electrolyte hardly becomes heated at all, and thus no other reactions occur and no chlorates are produced. Preferably, the apparatus is worked at the bleaching plant, where the solution is at once used in the bleaching vats, as it is not practicable to store and ship the hypochlorite. No other chemical is required in the bleaching vat, as the hypochlorite rapidly gives off its oxygen when it comes in contact with the pulp or textile fabric and passes back to common salt again. One of the great advantages over bleaching powder is that no insoluble precipitate is formed. For this reason, and because chlorine has been too strong for this purpose, it has been impossible to use bleaching powder in whitening high-class linen. At the present time all the best linens of Ireland are sun-bleached. A large Scotch linen company are now trying the use of hypochlorite. A brief reference is made to the fact that the addition of sulphuric acid to the hypochlorite solution releases chlorine and oxygen, and forms sulphate of soda. It is said to be probable that this would be a better source of chlorine for chlorination than bleaching powders, and at any mine where fuel, water and salt are obtainable such cells might be erected for the direct production and use of chlorine, both in treating gold ores and in leaching low-grade copper ores.

A description of another apparatus for producing bleaching liquids is given in the *Electrochem. Zeit.* for October, its chief advantages being cheapness of the product and simplicity. The apparatus may be compared with a staircase, each step representing a self-contained electrolysis. The salt solution flows down these stairs from step to step, while on each step the electric current flows through it from one side to the other. The plates of every step contain 22 slots each, in which there are imbedded "peculiarly formed bodies of platinum-iridium." The action of the new apparatus is said to be based primarily upon the fact that the salt solution is divided into thin liquid threads, and thus is subjected to the action of the current. Moreover, "the platinum-iridium bodies are so formed that the electrically polarized surfaces are not of equal size, as in all other electrolyses, but the electrode polarized by chlorine has a surface several times as large as the electrode polarized by hydrogen."

The financial state of affairs concerning the bleaching powder industry in England is discussed in an editorial note in the London *Elec.*, November 14th, which was prompted by the failure of the convention held by the English and foreign producers of heavy chemicals, which may be fraught with serious consequences for those of the new electrochemical works which depend upon bleaching powder for their profits. During the past four years bleaching powder has been maintained at an average price of $30 per ton by somewhat artificial means, and the electrolytic alkali works in this and other countries have benefited by the business arrangement existing between the English United Alkali Co., as representing the old Le Blanc process, and the Chemische Fabrik "Elektron," which is the German firm controlling nine tenths of the electrolytic production on the continent. Under this arrangement the latter firm were allowed to dispose of 6,000 tons of bleaching powder per year in the United Kingdom, and the immediate cause of the rupture is said to have been a request that this quantity should be increased to 8,000 tons. Whether this explanation be correct or not, the fact remains that there was a failure of the agreement between the rival producers, and contracts have been signed for the delivery of large quantities of bleaching powder in 1903 at the low price of $20 per ton, delivered at the consumers' works. Should the value of bleaching powder fall to $17.50 a ton, as some believe it may, the margin for profit in this product would be practically wiped out, and many of the electrolytic alkali works would find themselves in an unenviable financial position. The one consolation is that the older Le Blanc will also be severely affected by the fall of prices, and their owners will doubtless be prepared, after a short period of open competition, to meet their rivals half way in any proposals for the further regulation of prices.

*Alkali Industry.*—That prolific writer on electrochemical industries, J. B. C. Kershaw, begins another article in London *Elec.*, November 14th, in which he discusses the present condition of the alkali industries, beginning with that in the United Kingdom. This also bears on the subject of the bleaching industry, and on the overproduction of bleaching powder in Germany. The capacity of the Middlewich works of the Electrolytic Alkali Co. will be increased to 250 cells, and it is estimated that the output will then amount to 12,800 tons of bleaching powder and 18,000 tons of soda crystals per year. The Weston Point works of the Castner-Kellner Co. have paid a dividend of 6 per cent. for the last year. Both at Middlewich and at Weston Point the concentration of the alkaline liquors running from the electrolytic cells is carried out by means of multiple-effect evaporators. The total power available at Middlewich and Weston Point for the production of alkalies and chlorine products is now between 5,000 and 6,000 horse power, and when the additions to the Middlewich plant are completed over 7,000 horse-power will be devoted to the electrolytic decomposition of salt in that country. Should the whole of the chlorine liberated from the salt be converted into bleaching powder, the aggregate production of this chemical by the two electrolytic plants will be about 25,000 tons per year. In Germany, the group of electrolytic alkali works under the control of the Griesheim Co. "Elektron," situated at Bitterfeld, Griesheim and Rheinfelden, appear to be working satisfactorily. The new Aussig "bell" process is being operated at one of the Bitterfeld works, and it is probable that in course of time it will be generally adopted by all the works under the control of the Griesheim firm. At the Bitterfeld plant the annual output of caustic potash and bleaching powder is 7,200 and 12,250 tons respectively, and, in addition, considerable amounts of sodium and magnesium are produced. The output of the Rheinfelden plant is 5,800 tons of caustic potash and 10,000 tons of bleaching powder per year. The maximum output of the group of works at Griesheim, Bitterfeld and Rheinfelden is 25,000 tons of caustic potash and 40,000 tons of bleaching powder per year; and the electrolytic works of the Solvay Co., at Osternienberg, add about 5,000 tons to the latter total. The German home demand for bleaching powder is, therefore, more than covered by the output of the electrolytic plants, and the development of the export trade in bleaching powder is essential for the maintenance of the German electrolytic alkali industry. Already in 1900 the total exports amounted to 25,953 tons, while only 308 tons were imported.

*Furnaces.*—In the "Synopsis" of last month the method of Borchers and Stockem, for the production of metallic calcium, was described. This article has apparently brought forth a description of another method of ARNDT, by which he claims that the same result may be obtained with a more simple apparatus, which he describes in *Zeit. f. Electrochemie*, November 13th. He uses an iron crucible, which is coated inside with the material of fire-brick, mixed with water to a creamy consistence; the bottom is also covered with a layer of fluor spar, and the whole is dried in a warm place for twenty-four hours. A carbon rod is used as anode, and a thick iron wire as cathode, which is covered with a porcelain tube to about 4 cm. from its lower end, as shown in the adjoining diagram. To cool the crucible, it was placed on a large iron block. To fuse the calcium chloride, which, freed from its water, was gradually introduced into the crucible, an arc was used between the carbon anode and a carbon rod (not shown in the figure) held in the hand, and also connected to the negative pole, until the current passed through the bath; the current was then held at 20 to 25 ampères. After having beaten the contents of the crucible to pieces, he found metallic calcium in larger well-fused pieces, which could be easily hammered and filed. At fresh surfaces the metal is nearly white, but soon gets a yellow color. The analysis of a piece thus produced showed 99 per cent. of calcium and 1 per cent. of silicon, no iron or aluminum being present.



CALCIUM FURNACE.

DANNEEL continues, in the *Zeit. f. Electrochemie*, September 25th, the description of other processes which have been worked out in the metallurgical laboratory of the Institute of Technology of Aix-la Chapelle. Some notes are given on preliminary experiments of Borchers, which are to be continued on a large scale, for the production of chromium, free from carbon, in the electric furnace, chromic oxide being placed over a mixture of aluminium oxide with the amount of carbon required for the reduction. Experiments of Stockem are also described. He endeavored to produce cerium by electrolysis, the object being to utilize the waste materials of the gas incandescent lamp manufacture. Cerium is best obtained from the fused chlorides, free from water; less favorable results are obtained with the reduction of the oxide. By the Goldschmidt reduction process, cerium could not be obtained. Some experiments by Borchers and Dorsemagen are noticed on the preparation of red lead, or minium, from lead peroxide and lead oxide. Some

notes are also given on nickel refining, the modern "tops and bottoms" process being represented diagrammatically, and some modifications suggested by Borchers and Guenther being noticed. A detailed article by Guenther on this subject is promised in the near future.

*Testing of Alloys.*—Electrochemical methods seem to be gradually replacing former methods for doing various things. Sirks recently described such a method for testing alloys for industrial purposes, which description will be found in the *Proc. Roy. Akad., Amsterdam,* September 27th, a brief extract of which is given in the London *Elec.,* November 14th. Formerly the specimens were polished and exposed to a tempering flame. The different oxidizing action on the various constituents brings out the crystalline structure of the alloy and gives valuable hints concerning its mechanical properties. Instead of tempering, the metals may also be etched in acids, but this method has various disadvantages, owing to gas bubbles and the like. These difficulties have been removed in the electrolytic method of the author. The specimen is made the anode in an electrolytic cell, with copper as a cathode. Direct current at 4 volts is used; the electrolyte is water with six drops of dilute sulphuric acid per 100 cc. In this way the formation of basic metallic deposits is avoided. Since the etchings are much more pronounced in this method than in the simple acid etching, it is not necessary to polish the specimens; smooth filing suffices. It is possible to etch out individual crystals of the alloy, showing a definite and invariable proportion of the constituents. These crystals are the product of a chemical reaction between the constituents which has a profound influence upon the mechanical properties of the alloy.

*Recovery of Tin from Tin-Plate Scrap.*—The *Chem. Industry,* 1902, page 625, publishes a note on a Swedish patent of Bergman, which is abstracted in the *Eng. and Min. Jour.,* November 15th. He introduces the scrap into an iron vessel filled with a solution of caustic alkali, together with a depolarizer, but no copper oxide. Electrical action sets in; the scrap is stripped, and the tin goes into solution as a stannate of the alkali. When a saturated solution is obtained, the tin is precipitated as oxyhydrate by means of a current of carbon dioxide. The precipitate is filtered off, dissolved in acid and the tin is separated out electrically.

*Electrometallurgy.*—A series of articles by Beadle is published in the London *Elec. Rev.,* September 26th, October 10th and 24th and November 14th, on electrometallurgical problems, especially those discussing the methods which have been proposed for producing metals from the ores. The first three articles deal with copper, lead and zinc, but do not seem to give anything new. The last one is on the production of gold and silver.

## THEORETICAL AND EXPERIMENTAL.

*Artificial Diamonds.*—The experimental researches of Moissan, in which he produced true diamonds in the electric furnace, seem to have interested others in similar directions, and it is not at all unlikely that at some time in the no distant future diamonds may be produced artificially so much cheaper than the natural diamonds that much of the interest now lying in their possession may be lost. Ludwig seems to have had greater success than Moissan, at least in producing diamonds of larger size, as he obtained them as large as a pea. His experiments are described in the *Chem. Zeit.,* vol. 25, p. 970, an abstract of which is given in the *Am. Jour. Sc.* for December. His results may be of special interest, as it is his intention to develop the processes so as to manufacture diamonds on a commercial scale. It was shown by Pepys, in 1815, that an iron wire heated to redness in contact with diamond was converted into steel. The present author claims that, under great pressure, in an atmosphere of hydrogen this reaction is reversed, and also that carbon fused in the electric arc in the absence of iron, under the same conditions of pressure, is likewise converted into diamonds. In carrying out the experiments, pressures as high as 3,100 atmospheres were used. A spiral of iron wire was imbedded in powdered retort carbon and heated by an electric current in a highly-compressed atmosphere of hydrogen. In a few moments the resistance, which was slight at first, on account of the conductivity of the carbon, rose to that of the iron spiral. This indicated that the carbon in contact with the spiral had become non-conducting, and careful examination showed that on some of the pieces of carbon were brilliant, minute crystals, possessing the hardness, specific gravity and refraction of the diamond. The greater part of the carbon contained in the iron spiral had also been connected into diamond. The crystals had the characteristic irregular surface shown by the diamonds produced by Moissan by the sudden cooling of molten iron. To produce diamonds without the use of iron, it was found necessary to use much higher temperatures, and actually fuse the carbon under very high pressure. Thus fused, it was shown to be a non-conductor, and hence was considered to be the molten diamond. Under the pressure employed, this fusion took place very easily in the electric arc, and there were thus obtained spherical masses of the size of peas, having great hardness and crystalline structure.

*Electrolysis of Fused Caustic Potash.*—In the *Zeit. f. Electrochem.,* October 23d, Le Blanc and Brode give an account of their experiments, which are in the form of a continuation of their investigations of the electrolysis of fused caustic soda and potash, recently noticed in this Synopsis. In fused caustic potash the ions are K and OH, and the development of hydrogen at the cathode results from the presence of water dissolved in the fused bath. The values of the decomposition voltage are nearly the same as for caustic soda. From their experiments they conclude with positiveness that it is impossible by Castner's process, in the presence of air, to produce metallic potassium (as distinguished from sodium) from pure fused caustic potash on an industrial scale. They think that Castner probably worked only with fused caustic soda. The impossibility of producing metallic potassium by Castner's process is thought to be due to the fact that metallic potassium at that temperature oxidizes very easily.

*Lead as Anode in Sodium Hydroxide Solutions.*—Experimental investigations were recently made by Elbs and Forssell of the behavior of lead as anode in sodium hydroxide solutions and of the electrolysis of sodium hydroxide solutions containing lead oxides. The principal results are as follows: A lead anode dissolves in sodium hydroxide under different conditions, but always as bivalent lead. In the electrolysis of sodium hydroxide solutions, containing lead oxides with an inert anode, the primary electrolytic action at the anode is the discharge of lead oxide and oxygen, while lead peroxide is secondarily formed; hence the amount of peroxide formed per coulomb increases considerably with increasing temperature. Moreover, the speed of formation of the lead peroxide depends greatly on the material of the anode; the discharged anions have mostly the formula $HPbO_2$ (monovalent). Lead peroxide is formed upon a platinum anode at 20° C. at a voltage which is lower by 0.23 volt than that required for the formation of lead oxide and oxygen. Lead peroxide has, like platinum and some other metals, the property to occlude oxygen, and at a certain voltage the pressure of the occluded oxygen is probably the same as on platinum. The formation of lead peroxide and the re-formation of ions of bivalent lead from it in alkaline solution is not a reversible process. The experiments are described in the *Zeit. f. Elektrochemie,* October 2d.

*Electrolysis of Silver Nitrate.*—A note is published in the London *Elec. Eng.,* November 7th, stating that while it is generally said that silver nitrate becomes acid during electrolysis, yet Roger and Watson found that the acidity diminished. The apparent contradiction has been explained recently by Leduc as being due to a difference of the conditions. With platinum electrodes in a sufficiently-concentrated solution, a brown solid, containing a higher oxide of silver, is formed with the

simultaneous formation of nitric acid, which, however, when a sufficient concentration is reached, reacts on the compound with the formation of oxygen. Similar results are obtained with soluble anodes and a sufficient current density, and the acidity of the bath therefore leads to a limiting value. He finds that a corrosion or solution of the cathode deposit does not take place, and the experiments also indicate that in a silver nitrate voltameter the polarization e. m. f. is about 0.03 volt.

*Amalgam Potentials.*—REUTER gives an account in the *Zeit. f. Elektrochemie,* October 16th, of an experimental investigation of the electromotive behavior of potassium amalgams. Haber and Sark previously investigated sodium amalgams, and the present author found that his results correspond with theirs. His principal results are as follows: Potassium amalgams containing very low to high per cents. of potassium were prepared, and their potentials were measured in a solution of 1.50 per cent. $LiCl$ in methyl alcohol. The other electrode was Ostwald's well-known mercury standard electrode. The measurements were made at —80° C. The results are plotted in the form of a curve, which shows a characteristic and large break in continuity at the point corresponding to the alloy $Hg_{12}K$. The potentials have about the position in the curve which they should have according to Berthelot's rule, the heat of formation measuring the change of free energy. The potential of pure potassium and pure sodium is lowered considerably by slight additions of mercury.

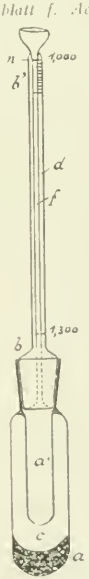
*Reduction by Calcium Carbide.*—As is well known, this material may be used for the reduction of metallic oxides and salts, the action being similar to that of aluminum, but much more powerful. There seems to be some doubt, however, about the formula representing the process, and this is of practical importance, as it shows the quantities required, which may decide whether or not a process becomes practicable. Two papers have recently been published, one by NEUMANN, in the *Zeit. f. Elektrochem.*, October 2d, and another by VON KNEGELGEN, in the same journal, October 9th. Both have investigated its action, but have reached different conclusions concerning the formula. The formula found by the latter requires considerably less carbide for the process, and it therefore appears less hopeless for practical application. The principal difference between the views of the two authors is that Neumann assumes that primarily carbon monoxide is formed, while von Knegelgen assumes the primary formation of carbon dioxide. Neumann has made some gas analytic measurements, and claims that they prove the correctness of this view; von Knegelgen denies that this is proved by those measurements, and promises the publication of a more detailed study of the problem.

*Oxidation Processes.*—BODLAENDER has written a long article, in the form of a contribution to the theory of some technical reduction and oxidation processes. It seems to contain very valuable figures, but cannot be abstracted. It is published in the *Zeit. f. Elektrochemie,* October 30th. At the end of the article the author gives the most important interpolation formulas for the free formation energies, relating to the oxidation of carbon to carbon dioxide, the oxidation of carbon to carbon monoxide, the oxidation of carbon monoxide to dioxide, the formation of carbon monoxide from carbon and carbon dioxide, the combination of hydrogen and oxygen, the oxidation of zinc, the oxidation of iron and the formation of hydrochloric acid from hydrogen and chlorine.

*Maxwell's Theory and Electrolysis.*—In the *Electrochem. Zeit.* for September PLATNER concludes his mathematical article on Maxwell's theory of electricity and its importance in the theory of electrolysis. The electrolyte is compared by him with Maxwell's dielectric medium. The electric force produces in this medium a condition similar to elastic tension (dielectric displacement). There are pressures produced in the medium which result in mechanical motion, there being a tension along the lines of force and a pressure perpendicular to the lines of force. He adds the supposition that the different materials of the electrolyte react in a different manner against these forces, and thus gets what he believes to be a basis which is quite sufficient for the explanation of electrolytic phenomena without the use of any "fantastic hypothesis."

*Chemical Effects of Canal Rays.*—G. C. SCHMIDT recently published an account of an experimental investigation in which he endeavored to find whether positive ions in gases exert an oxidizing action. This might be expected, as the negative electrons in cathode rays are known to have a strong reducing effect, which has been explained by the assumption that the negative electron satisfies a positive valency of the metallic atom, so that this requires a lower valency than before. By an argument based on analogy, it might be expected that canal rays, which are assumed to consist of positive ions associated in some way with neutral atoms, would exert an oxidizing action. The author did not, however, find any well-defined oxidizing action. There is powerful decomposition, but it depends upon the nature of the gas and the compound whether the decomposition results in an oxidation or in a reduction. Solid solutions which show luminescence under cathode rays show the same under canal rays, but it decreases rapidly, owing to the decomposition, which is indicated "by the spectrum of the glow becoming whitish." If the gas in the tube is oxygen, and an oxidizable body is in it, the latter is oxidized. If, on the other hand, the gas is hydrogen, the latter reduces any compound capable of reduction. The most typical reaction for canal rays is the decomposition of sodium compounds; it takes place even when only traces of sodium are present, and is revealed by the D line. The article may be found in the *Ann. d Phys.*, November 11th, and is abstracted in *London Elec.*, November 14th.

*Determining the Specific Gravity of Liquids.*—The *Centralblatt f. Accum.* of November 1st publishes an illustrated description of a new "araeo-pyknometer," devised by RAIKOW, which enables one to easily determine the specific gravity of the same small quantity of a liquid at different temperatures in succession. As will be seen in the adjoining illustration, the instrument consists of two parts, the lower one *a a'* and the upper one *b b'*. The lower one is divided into three portions: the lowest *a* is filled with mercury, the second *c* is empty and the third *a'* contains the liquid the density of which is to be determined. The upper end of the latter forms a neck, into which the upper part of the apparatus is set in like the stopper of the neck of a bottle. This upper part consists of two tubes *d* and *f*, the latter being thin, of a diameter of about 1 mm., and placed in the central part of the tube *d*. The two tubes are fused together at the two ends. The instrument is used as follows: The upper part is taken out, and the portion *a'* is filled with the liquid to be tested so that it reaches somewhat into the neck, then the upper part of the instrument is put into the neck, and the whole instrument is placed into water of the desired temperature. The liquid is then drawn out of the upper funnel until it reaches the mark *n* on the scale, with which the tube *d* is provided. Then the floating capacity of the araeo pyknometer is determined in distilled water in the ordinary way, the specific gravity of the liquid tested being read from the scale. When the specific gravity of a liquid at a certain temperature has been determined, and one wants to find it at another higher temperature, it is only necessary to raise to the desired amount the temperature of the water in which the instrument floats and to again adjust the liquid level in tube *f* exactly to mark the *n*. In case one wants to determine the specific gravity at a lower temperature, one first adds one or



ARAEO-PYKNOMETER.

...ings of the liquid into the funnel and then cools the ...ter to the desired lower temperature, all other operations ...ing as before.

*Physical Chemistry.*—Several papers have recently been published on the application of electrochemical methods to special ...ects in inorganic chemistry: one by Loeb, in *Zeit. f. Elektro...*, October 2d; another by Elbs and Brand, Elbs and ...ammer and Klempert, in *Zeit. f. Elektrochemie*, October ...d; a third by Escherich and Moest in *Zeit. f. Elektro...*, November 6th.

## PRIMARY AND SECONDARY BATTERIES.

*Batteries for Electric Launches.*—The scant literature on batteries during the past month contains an illustrated description by Dreihardt of the electric launches exhibited at the International Self-propelled Boat Exposition, at Wannsee, Berlin, 1902. The number of cells in these boats is generally 40 or 80, in order to be able to charge the battery directly from a 110 or 220-volt station. Occasionally boats with 200 cells have been made for charging from 550-volt stations. The charging is nearly always done with constant voltage and variable current, which enables one to complete the charge more quickly and with less attendance. The largest of the three boats exhibited has a battery of 80 cells, each having 15 positive Planté and 16 negative Faure plates. The capacity is 450 ampere hours for a six-hour discharge. The total weight of the battery is 7,000 kg. The description is given in the *Centralblatt f. Accum.*, November 1st and 15th.

*Explosion in a Storage-Battery Plant.*—There were two accidents recently, of a somewhat serious nature, in some storage-battery plants in Germany, which were due to the explosions of the hydrogen and oxygen produced electrolytically in the batteries and used for soldering purposes, a practice which seems to be becoming common in German accumulator works. A description of these accidents is published by Schoop in the *Elec. Zeit.*, November 6th. He recommends taking care to exclude all organic substances from contact with the oxygen, and to use nothing but water for lubricating the valves; also to take care to keep the receptacles for the oxygen and hydrogen separate from each other, so that no mixture of the gases, by carelessness or otherwise, may take place.

*Storage Batteries at the Dusseldorf Exposition.*—London *Eng'ing*, September 17th, continues the long serial on the chemical and metallurgical industries exhibited at this exhibition. It seems that the electrochemical exhibits were confined to storage batteries, and in the present portion those exhibited by various German firms are described.

## GENERAL AND MISCELLANEOUS.

*Water Power Plants.*—A number of large power plants, ...tended more particularly for electrochemical processes, were described during the past month. Among these there is an illustrated description in *L'Ind. Elec.*, October 10th, of the Clavaux plant of the Société d'Electrochemie. The 5,000 horse-power is available during eight months, while at low-water level the available hydraulic power decreases to 3,000 horse-power. The horizontal axle turbines have a capacity of 550 horse-power, the normal speed being 250 revolutions per minute. There are five 375 kw. direct-current generators direct coupled to the turbine. A small 80 kw. generator furnishes the current for light and for various motors in the plant. Each of the 375 kw. direct-current generators is provided with two independent commutators, each giving 2,500 ampères and 75 volts. Only three generators are at work at present. The purely electrolytic processes are mainly for the production of sodium and peroxide of sodium by the Castner & Hulin method.

Several plants in the Alps are described in the *Elec. Age* for December, forming a third part of a series of articles. The French electrochemical and electrometallurgical industries have their principal centre of activity in the region of the Alps. This article first gives a list of 17 power houses, of together 74,000 horse-power, a large portion producing calcium carbide, besides chlorates, aluminum and sodium. Some notes are also given on the installation of the power houses at Giffre, at Chedde, at Chapareillan, at Pontcharra and on the Arve.

The Sault Ste. Marie power house is described in *Cassier's Mag.* for December, by von Schoen.

*Fused Quartz.*—The very great advantages of the use of quartz in place of glass, namely, its great strength, the fact that it can be heated to about 1,400° C. without changing its shape, and the fact that such vessels can be heated without cracking, make the subject of the production of articles in fused quartz a very attractive one, and one which it seems promises to be developed in the near future by means of the electric furnace. Quartz may be welded, blown and shaped just like fused glass, the only difference apparently being in the fact that a very high temperature is required for its fusion, and, unless well fused, difficulties arise in the production of bubbles in the mass. Heraeus, in Germany, has succeeded in making such apparatus by means of the oxyhydrogen flame; Shenstone has worked in Great Britain with the same flame; Hutton, of Manchester, England, has worked with the arc, as was described in his recent Electrochemical Society paper at Niagara Falls. According to the *Zeit. f. Elektrochem.*, November 13th, another German firm now make such articles commercially, although the price is still rather high and the production of small air bubbles in the mass cannot yet be entirely avoided.

*Removing Hair by Electricity.*—It seems that the electric method of removing hair so that it will not grow again has proved to be the surest, although it is at the same time the slowest, process. It is described in the *Arch. d'Elec. Méd.* for October 15th, in an article by Guilloz, which is abstracted in London *Elec.*, November 14th. The cathode is in the form of a fine needle of platinum, gold or, best of all, steel. It is introduced into the skin alongside of the hair to the bottom of the bulb, and a current of 1 or 2 milliampères is passed for a time varying from twenty to fifty seconds. The action is said to be that of a galvano-cautery, but the account also says that hydrogen is disengaged around the end of the needle and appears as a white foam, and it may therefore be electrolytic. It appears that the destructive action will affect the roots of the hair, even though the needle may not be in actual contact.

*Electrolysis and Physiology.*—Berthelot, in *Comptes Rendus*, September 29th, gives an account of an investigation of certain voltaic cells whose behavior has an important bearing upon the physiological action of the animal cells composing the human body. He studied more especially the very small chemical transformation accomplished in a single animal cell during the impact of a single blood wave. An abstract is given in the London *Elec.*, October 31st.

*Standardization of Methods of Chemical Analysis.*—Blount, in a paper in London *Eng'ing*, November 7th, draws attention to the growing demand for standardization. While necessary for such quantities as weights, money, etc., the desirability of standardization is less incontestable for wire and sheet gauges, screw threads, etc., debatable for the dimensions of rails and rolled joists and doubtful for the testing of materials used in construction. Passing to the standardization of chemical analysis, he draws a distinction between the provision for standard samples of steel and the establishment of standard methods of analysis. The discordance of views held by chemists on standard methods is, to some degree, due to want of mutual understanding. The arbitrary methods in use for the examination of water, milk, oils, foods, manures, etc., should be standardized, but true analytical processes, such as the determination of all elements and most inorganic and many organic bodies, cannot be. Standard methods for the determination of a chemical entity cannot be imposed upon trained chemists. Yet he advocates conferences of specialists in dif-

ferent branches of analysis for the discussion of methods, though not for the promulgation of rules. The agitation for standard methods has arisen in a great measure from the occurrence of discrepancies in analysis, due to bad sampling and unskilled work, which cannot be remedied by standardization. With good sampling and skillful work, uniform results will be obtained, irrespective of uniformity of methods. The chemist, he thinks, should be better trained and better paid.

*Dusseldorf Exposition.*—DANNEEL continues his illustrated serial on the electrochemical exhibits in the *Zeit. f. Elektrochem.*, October 16th and 23d. Several instruments of Hartmann & Braun and electric laboratory furnaces of Heraeus are described and illustrated, and some data are given on power gas installations.

*German Electrochemical Patents.*—Some statistical work of the German Patent Office during the past ten years is given in the *Electrochem. Zeit.* for October.

*Owens College Laboratory.*—The electrochemical laboratory at this college in Manchester, under the direction of R. S. Hutton, is described by WALKER in the *Eng. and Min. Jour.*, November 15th. This is the first laboratory in England for study and research of electrochemistry and electrometallurgy.

*Electrochemical Engineering.*—Under the title of "Elektrochemisch Technik," the *Centralblatt f. Accum.* now publishes a supplement in the form of the repertorium of new articles, papers, patents, etc., on electrochemistry, arranged in alphabetical order.

## *Book Reviews.*

ELECTROCHEMICAL ANALYSIS. By Prof. Edgar F. Smith. Third edition, revised and enlarged. 204 pages, illustrated. Philadelphia: P. Blakiston's Son & Co., 1902. Price, $1.50.

There is probably more accurate and exact information on the general subject of the electrodeposition of metals inside the covers of a treatise on electrochemical analysis than in any other kind of publication. After wandering through the maze of poorly-arranged, uncritical and indefinite information on this subject, such as is found in most works on "electrometallurgy," it is wonderfully refreshing to find exact quantitative data, obtained under test conditions, with all the accuracy of description and operation required by the exigencies of quantitative chemical analysis. To any such wanderers, who may have come to feel perhaps that electrometallurgy is largely a rule-of-thumb trade, a perusal of such a book as this of Professor Smith's is heartily recommended as an anti bilious corrective.

While not so pretentious as Classen's work on the same subject, the work, as a book of instruction, is probably more useful. The author describes many home made devices and laboratory arrangements of his own in such familiar style as causes the difficulties of the subject to vanish, and puts the student at once at his ease; he is being instructed by a practical co-worker. The introductory chapters on the action of the electric current on salts, the definitions of electric current, sources of the current, resistances, measuring instruments, description of laboratory and historical sketch of the subject, are all interestingly written, but in some cases the striving for brevity and conciseness has been at the expense of completeness, and a few more pages on some of these heads would have avoided ambiguity and given the student a more just appreciation of the subject.

In the determination of the separate metals and separation of metals from each other, nearly every page contains the complete data and results of critical tests of the methods described, made by the author or his students. Diagrams of the arrangement of apparatus are supplemented by photographs of the apparatus in actual use, taken by Mr. Taggart, and references to the literature of the subject are abundantly given. In the reviewer's opinion, this part of the book (which is, after all, its essential part) is not equaled by any other publication on electrochemical analysis, and will be of great service to every electrochemist, be he purely scientific or practical.

The author speaks, on page 102, of using a current of "2 ampères *per minute*," a mistake which has been carried over from a former edition, and which ought to be corrected. The author's definitions of *volt* and *ampère* need defining more closely, as in their present state they suggest the predicament of the hero of the "Nonsense Book," whose utmost endeavors to find the difference between a *snark* and a *boojum* resulted only in the information that "a *snark* is a *boojum* and a *boojum* is a *snark*."

MONOGRAPHIEN UEBER ANGEWANDTE ELEKTROCHEMIE. Vol. II. Die Gewinnung des Aluminiums und dessen Bedeutung fur Handel und Industrie. By Adolphe Minet. Translated into German by Dr. Emil Abel, Halle a. S.: Wilhelm Knapp. 129 pages, with 57 illustrations and 15 tables. Price, marks 7.

The present volume is the second one of the series of "Monographs on Applied Electrochemistry," edited by Victor Engelhardt, chief engineer of the Siemens & Halske Co., of Vienna. The author is Adolphe Minet, the inventor of the Minet process, who for a number of years has devoted his attention to the manufacture of aluminum. The book is divided into two parts, the first dealing with the production of the metal, the second with its physical properties, alloys and applications in the arts. In the first part the author takes up, in the order named, the chemical methods, with and without the use of sodium, the electro-thermic and the electrolytic methods. The most interesting part of the book for the electrochemical public is the one which is devoted to a description of Minet's own methods and experiments. These are described at length, and various interesting data are given. It is worthy of note that Minet still clings to the opinion about the reactions taking place in his process, which he expressed in his first patent, in 1887, namely, that aluminum fluoride is primarily decomposed by the current. While he devotes over 20 pages to his own process, he treats the Héroult process, which is a great deal more important than his own, on four pages, and the Hall process, which is at least as important as the Héroult process, is dismissed with about 30 lines and a reprint of half a dozen of schematic patent specification figures, either taken from Mr. Hall's patents or from Borchers' "Electrometallurgie." The description of the other processes, besides these three, is given in condensed form, following in the main the exhaustive treatise of Prof. J. W. Richards on "Aluminium" and Borchers' "Electrometallurgie," and the majority of illustrations given in the latter under the head of aluminum are reproduced. In marked contrast to both of these authors, however, Mr. Minet frequently omits to enumerate the specific references to his sources of information, and merely mentions the names of his authorities. There is also a great discrepancy between the figures of the production of aluminum in the various countries which he gives and those that are given at other places. For instance, he gives as the production in 1900, United States, 1,650 tons; Switzerland, 1,232 tons; France, 800 tons, and England, 500 tons. The production as given in the *Mineral Industry*, Vol. XI, 1902, for 1900 is as follows: United States, 3,243 tons; Switzerland, 2,500 tons; England, 500 tons, and France, 1,500 tons.

Considering the book as a whole, one cannot fail to feel that the expectations which the name of the author on the title page might have given rise to have not been fulfilled. As a textbook, it cannot compare with J. W. Richards' presentation of the subject in his well-known work on "Aluminium." Coming, however, as it does from a man who has had a great deal of experience in the manufacture of the metal, it cannot fail to be of interest to anybody who is familiar with the subject, and, despite its shortcomings is well worth a perusal.

Elementary Chemistry. By F. W. Clarke, Chief Chemist of the United States Geological Survey, and L. M. Dennis, Professor of Inorganic and Analytical Chemistry in Cornell University. New York: American Book Co. 340 pages and 51 illustrations. Price, bound in cloth, $1.10.

In this small volume the distinguished authors present an elementary text-book of chemistry, intended to be used by two classes of readers: First, those to whom chemistry is only one item in a general education, and, secondly, those who intend to take a more advanced course in chemical training. For the first class the book is sufficiently full; for the second class it is intended to serve as a legitimate basis for subsequent higher study. As the authors remark in the preface, "the study of chemistry, apart from its scientific and detailed applications, is a training in the interpretation of evidence, and herein lies its chief merit as an instrument of education." This idea is constantly kept in mind throughout the book. A reasonable number of experiments are described, and each generalization is made to follow the evidence upon which it rests.

The subject is rendered attractive and interesting to the student by constant references to the application of chemical science to human affairs, its utility in modern life, the technical methods of manufacture and the various uses of the substances discussed; 266 pages of the book deal with inorganic chemistry, 58 pages with organic chemistry.

Electrolytic action is very briefly and somewhat vaguely discussed on pages 163 to 167, but more can hardly be expected in an elementary text-book of chemistry. Page 167 contains the statement: "Most bases and most acids contain hydroxyl, OH, and when they unite they do so with evolution of water." According to modern ideas, the characteristic feature of a base is that it contains OH ions, and the characteristic feature of an acid that it contains H ions; in the formation of a neutral salt from an acid and a base, the H ions of the former and the OH ions of the latter combine directly to water.

The methods of electroplating and electrotyping, also the electrorefining of metals and the electrolytic manufacture of aluminum are noticed.

On pages 10 and 11 the term "force" is used in a very indistinct way. The authors speak of the conservation of force, instead of energy. They say that "such things as heat, light, electricity, mechanical power, etc., are called forces." Later on force is used in its correct sense.

## THE PRESENT POSITION OF THE STORAGE-BATTERY INDUSTRY IN GERMANY.*

In the manufacture of storage batteries by the big companies, a tendency has prevailed in recent years to disregard inventions which were enticing from a theoretical point of view, but seemed to be of questionable value for the practice, and the principal aim was to make a cell of a construction as simple as possible. The result has been that the cells made by different firms are so similar that the selling of storage batteries might be called, in the strict sense of the word, a trading in lead. The position of the buying agent has become the most important one.

The raw materials are lead, sulphuric acid and glass. No saving can be accomplished in the purchase of the glass, which represents only a small fraction of the total cost. Sulphuric acid is made in many plants as a by product at so low a cost that the prices differ only slightly. Thus the most important point is to buy the lead cheaply.

About a year and a half ago the price of 100 kilograms (220 pounds) of pure soft lead (purity 99.98 per cent.) was marks 37 ($9.25). To-day the greater firms have made contracts by which they get the lead at a price of marks 21 to 25 ($5.25 to $6.25). The price of the lead has fallen step by step, and it is not impossible that it may even fall further. The American Lead Trust is not likely to change this condition. On the one hand, Australia's and Spain's inexhaustible lead mines are strong competitors, as lead commands cheap freight rates, owing to its use as ballast in steamers. On the other hand, German silver and other mines produce large quantities of relatively very good lead at low prices. Neither will the duty proposed in the new German tariff be of great influence. It may be that the prices will rise slightly. In the next few years the German storage-battery manufacturers may have nothing to fear from the competition of foreign industries, which are still in their infancy. Should the lead price rise again to its former value, the only result would be that the consumer has to pay more.

In the purchase of lead, cash payments are the rule. The electrical energy for forming the plates and the wages for the workingmen also require cash payments, and the firm which promptly pays gets the lowest prices. It is therefore evident that only those storage-battery manufacturers who possess large reserves of floating capital can manufacture with profit. Recently the general manager of a Southern German storage-battery plant of good reputation stated privately that, at the present low prices, the plant sells its batteries with loss.

The development of the German storage-battery industry in recent years has already resulted in failures of several smaller companies, and this development will continue, with a stubborn fight of the surviving firms to the finish, if the leading managers don't prefer to unite. The "Cartell" (syndicate), which had been formed last year, has found a sudden death, as it was founded on a wrong basis. As it is easier to induce three competitors to unite than fifteen or more, the time will be ripe for a syndicate when still more companies will have failed, and the few survivors, after having fought bitterly, will recognize that they are of equal standing. The result will be a trust, and, as long as its members don't disagree, no outsider will be able to succeed in establishing himself in the industry if he has not a capital of several millions.

Better conditions prevail in the sale of automobile storage batteries, but the demand is not great.

* Translated from the *Centralblatt für Accumulatoren-Elemenlen und Accumobilenkunde*, Oct. 15

## AMERICAN AUTOMOBILE BATTERIES.—I.

### THE SPERRY BATTERY.

In the Sperry battery, which is manufactured by the National Battery Co., Buffalo, N. Y., the grid, as shown by Fig. 1, is made of thin, pure sheet lead, which is corrugated horizontally. In the bottom of the hollows, formed by the corrugations, numbers of small trapezoidal holes are punched. The punch also cuts diagonally across the trapezoid, and, instead of making a clean hole, fins are left which project on either side of the plate. The whole plate, when punched, resembles a corrugated grater, except that the fins are longer and triangular in shape. These projections are then spread wider apart, so that a pressure on the plate will cause them to bend down in a direction away from the holes from which the fins project.

The material which is to become active is spread in the form of a powder on both sides of the grid, filling up the corrugations and being in sufficient quantity to make a flat plate of usual thickness after press-welding. The whole is then subjected to pressure—about 1,000 pounds per square inch of surface—which forms it into a solid mass. The material is bound to the grid by being pressed together into a continuous mass, which is on both sides of the grid and is welded through the multitude of small holes, thereby riveting itself in the grid. Additional hold is furnished by the fins, which bend down and are clinched over the active material, and thus retain the material at the surface.

The retention by the fins and riveting under pressure of the powder into a solid mass cannot be successfully accomplished with every form of material to become active, but the material

used in the Sperry battery welds up strongly in the press, and, after the chemical formation, becomes hard like soap-stone. This active material consists of 80 to 85 per cent of finely-divided pure lead, obtained by dissolving a precipitation, to which is added 15 to 20 per cent of lead oxide. These are thoroughly mixed, and to the mass thus formed is added about one-twenty-fifth of a compound of alkaline salts and other ingredients.

The alkaline salts and other ingredients are themselves inert, and their function is twofold:

First. They decompose or dissolve when the plates are subjected to the acid bath, just before being subjected to the electrolytic forming process, leaving numerous minute cells throughout the mass of material upon the plates, which cells permit the electrolyte to thoroughly penetrate the mass of material upon the plates during the time they are subjected to the forming process, and also permit the expansion of this

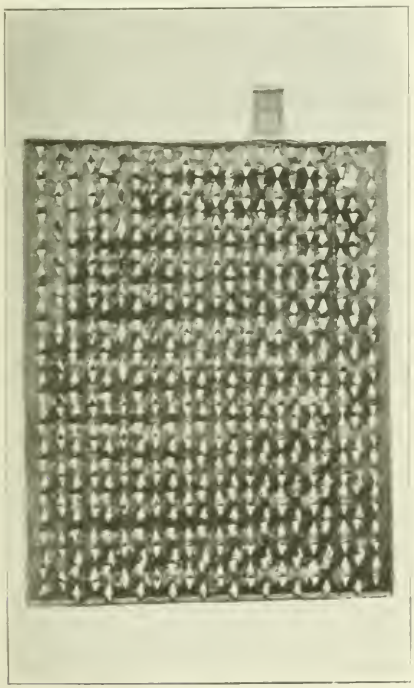


FIG. 1.—GRID, SPERRY BATTERY.

mass of material during the expansion which takes place in the material while the plates are subjected to the forming process, and thereby prevents the active material from crowding off or disintegrating from the grid or support and seriously injuring the plates.

Second. They have the peculiar property of causing the mass of material to harden, not only during the time that the plates are subjected to the forming process, but also during the use of the plates in a storage battery. In other words, this mixture accelerates the forming of the plates by increasing the penetration of the electrolyte, and also prevents serious injury to the plates that otherwise would be caused by the expansion and contraction of the mass of material; and, as above stated, also increases the hardening condition of the mass of material during the use of the plates.

The composition of the active material used, its method of application and the formation of the Sperry battery are such, however, that trouble from disintegration and dropping away of active material is obviated. There are a number of these batteries that have been in use for over two years, and the positive plates are hard, solid and durable.

The corrugation of the grid horizontally allows proper expansion, and relieves the plate of any tendency to buckle. As an additional precaution, however, the Sperry pyroxylin envelope is used, which is applied to the outside of the plate and covers it, passing down one side, under the bottom of the plate, and up the other side. It is evident that if any active material should be loosened by any extraordinary circumstance, it would not be able to drop off the plate, being held in position by the outside coating. If a particle of material should, by any chance, drop off, it is retained in the pyroxylin envelope and will not be able to short circuit the battery.

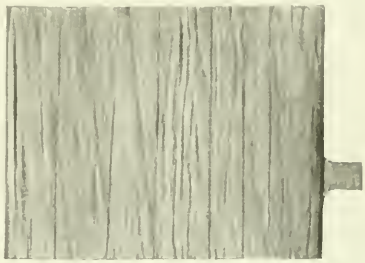

FIG. 2.—PYROXYLIN ENVELOPE.

This covering, or pyroxylin envelope as shown by Fig. 2, is made of open-mesh cotton cloth, such as "cheese cloth," which is chemically treated, forming a cellulose nitrate, which is termed "pyroxylin," and which is of the same general character as gun cotton. The addition of a small quantity of nitrobenzol renders it inert.

The jars in which the elements are placed are of the hard rubber variety, but different from the usual hard rubber jars in that they have a series of ribs, capped with soft rubber, extending across the bottom of the cells. On these soft, resilient ribs rest the plates, which are in this way relieved from excessive shock or jar. The separators are corrugated, perforated, ribbed, hard rubber.

Fig. 3 shows a curve of discharge of the Sperry battery taken from 44 cells in series. These cells weigh 1,005 pound

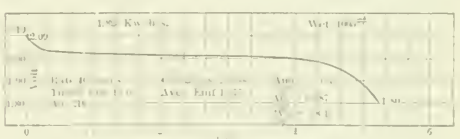

FIG. 3.—SPERRY BATTERY DISCHARGE.

gross, or 23 pounds each. The discharge rate was nearly 40 ampères, and the average voltage 1.975. The curve shows the unusual results of 1.75 ampères, 9.187 ampère hours and 18.15 watt hours per pound gross weight at 5¼-hour discharge, giving, at this rate of discharge, 40 pounds per horse power hour, corresponding to an energy sufficient to raise its own weight against gravity at sea level about 9 miles.

This is equivalent to 2.65 ampères, 7.95 ampere hours, 5.03 watts and 15.09 watt hours per pound at the three hour rate. There are several sizes of these cells manufactured, the principal ones being 2 9-10 x 5½ x 10 inches, and weighing 15 pounds, gross; 2 x 7¼ x 10½ inches, and weighing 18 pounds gross, and 3 x 7¼ x 10½ inches, weighing 23 pounds.

A great number of life tests have been made on this battery, both in laboratories and on vehicles and in practical work.

One vehicle made 7,770 miles with the batteries at a loss of 28 per cent. of the original capacity when the test was discontinued. Several of the Sperry batteries have been in operation actively for over two years, and showed splendid results. The negative plates were apparently as good as when the battery was made, and a test conducted under the general supervision of Prof. John W. Langley, of the Case School of Applied Science, shows that the battery carried through a uniform rate of discharge of 1 ampère per pound until the carriage had run the equivalent of 3,000 miles. This test shows the capacity of the battery for the last ten discharges to be 10 per cent. in excess of the first ten discharges. The battery had not revealed any indication of falling off in capacity, and the forty-fourth discharge of this battery, taking it at 1 ampère per pound of complete working cell, is a mean potential difference throughout the curve of over 2 volts, namely, 2.014, as shown by the following fifteen-minute readings of potential difference and positive and negative cadmiums:

| Time. | Voltage between Plates. | Voltage between Positive Plate and Cadmium. | Voltage between Negative Plate and Cadmium. |

The company also manufacture a battery for automobile purposes, known as the "National." This battery is a combination of Sperry negative and Planté positive plates. The negative plates are 3-16 inch in thickness, and the positive plates ¼ inch in thickness. The former are made as explained in the description of the Sperry battery. The latter are made from chemically pure sheet lead, rolled to the desired thickness, cut into strips or ribbons and passed through machines of special design, which knurl and weave a straight and corrugated strip alternately. The ribbons are then placed in a form and subjected to hydraulic pressure, fitting them to the frame or grid, which is cast from an alloy of antimony and lead in

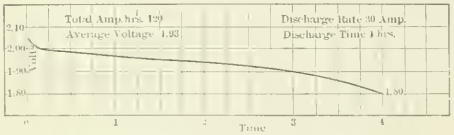

FIG. 4.—SPERRY BATTERY DISCHARGE CURVE.

two pieces. They are next placed in the grid, the center supports and ends of which are burned together, making the plate one piece.

The plates are electrochemically formed by the usual Planté method. Fig. 4 shows the discharge of 24 cells of this battery after 80 discharges, and the battery shows no sign of deterioration. Fig. 5 is the "National" positive plate.

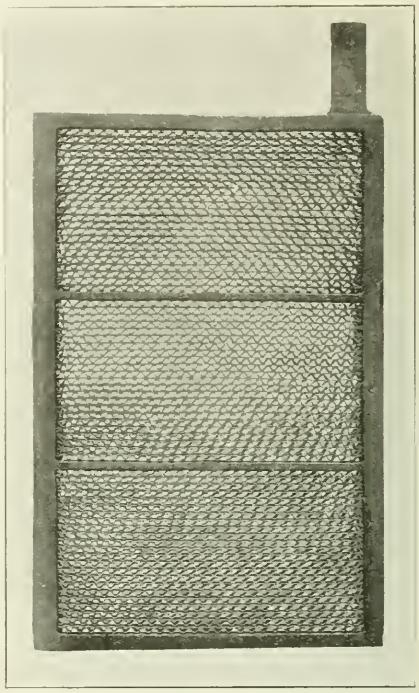

FIG. 5.—NATIONAL POSITIVE PLATE.

The extremely large surface secured by this method of construction makes it possible to obtain the capacity desired with a thin, hard, coherent layer of active material, and permits a free flow of the electrolyte through the plate, allowing it to withstand rapid charging and discharging without serious injury.

### WESTERN STORAGE BATTERY.

The more completely the active material covers the conducting plate or grid, the more enduring is the plate, more especially the positive electrode. For this reason the grid used in the Western storage battery, made by the Western Storage Battery Co. for the National Vehicle Co., Indianapolis, Ind., has a conducting diaphragm of thin, perforated lead running through the center of the plate, just midway between the surface of the outer frame of the plate; then, horizontally across this diaphragm are cast thin lines of lead, the outer edges of which are turned down, so that a slight shoulder is made, under which the oxide paste, to become active, is forced by hand pressure, thus confining the paste against outward pressure, which takes place in the process of forming the positive plates. When the plate is thoroughly pasted, small points of lead only show on the surface. Thus the forming process, in which the electrical current tends to follow the more prominent lead as its easiest line of conduction, is forced to seek the main conductor in the center of the plate, passing through the oxide paste to reach it, and producing the necessary chemical changes on its way. This tends to form the electrodes more evenly. The plates made in this way are light, but stiff, and, being cast of an alloy of lead and antimony, are less rapidly decomposed by the constant action of electrolysis in charging and discharging than soft lead would be. A plate, for example,

of a surface area of 4⅞ x 7¾ weighs 11 ounces, and will hold, when properly pasted, about the same weight of lead oxide paste when dry. Seven of these plates, when formed and charged, have a capacity of 68 to 70 ampere hours when discharged at the high rate of 20 amperes per hour.

In order to give more endurance than is usual in a light battery, the positive electrodes are protected from washing, which the motion of the vehicle gives to the battery electrolyte, by a thin pad of spun glass, made for this purpose. It is held against the two surfaces of the positive plate by perforated hard rubber, on one side of which are several perpendicular ribs, about 1-16 inch thick and ⅛ inch high. This gives free circulation of the liquid and gas along the negative plate, and also holds the very resilient glass pad firmly against the positive plate. The combination of spun glass and hard rubber for separators and insulators has proved an improvement, since there is no chemical action in this material, as there would be in any form of wood or cellulose, which chemical action, set up by electrolysis, is always detrimental to the durability of the lead grid. The following data are the results of a test of a 40-cell battery, each cell weighing 14½ pounds, complete. This battery was made up for the National Vehicle Co., for their road wagon, designated in the list as R 2 battery, and consists of seven plates, three positives and four negatives, the plates having each a surface area of 4⅞ x 7¾ inches. The specific gravity of the electrolyte was 1.250 fully charged, and 1.117 at the end of the discharge:

| Time. | Ampères. | Volts. |
|---|---|---|
| 12. | 20 | 82 |
| 1. | 20 | 81 |
| 1.30 | 20 | 80 |
| 2. | 20 | 79.5 |
| 2.30 | 20 | 78.5 |
| 3. | 20 | 77 |
| 3.30 | 20 | 75 |
| 3.45 | 20 | 68 |

This gives, for a 3¾-hour discharge, 75 ampere hours, with an average power of, approximately, 1,600 watts. At 68 volts the discharge is cut off and recharging at once commenced, since the drop to 68 volts for the series of 40 cells shows 1.6 volts to each cell, which is as low as any battery could be discharged.

The next size of battery, made for stanhope vehicles and park traps, contains the same number of plates, the surface area of which is 5 x 8¼ inches, and the discharge rate is 25 amperes, instead of 20, for 3¾ hours, which gives 94 ampère hours. Forty four of these cells, after making a trip over country roads for three days, of about 65 miles each day, charging in this time three times, made a run of 118 miles the day after charging on the asphalt streets of Indianapolis, taking about eleven hours for the test. In other respects, this battery does not differ outwardly from other batteries in general use.

### SMITH STORAGE BATTERY.

The tray storage battery, invented by Malcom O. Smith, and made by the Smith Storage Battery Co., Binghamton, N. Y., differs in its form widely from the batteries made by other manufacturers, although it involves no new principle. The main new point is that the jars are dispensed with, and the lead plates themselves are used for holding the electrolyte. The gridded plates are formed into oblong trays, with pointed bottoms, the ends also receding from the top to the bottom, so as to permit of nesting.

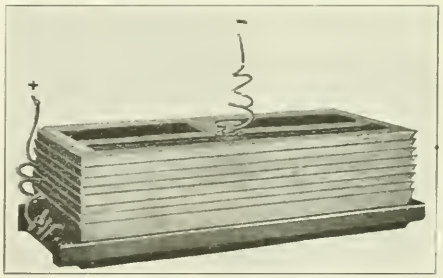
Any desired number of trays can be nested on top of each other, perforated separators of sheets of hard rubber or other suitable material keeping the trays from contact with each other. When nested, there is sufficient space between the trays to hold the electrolyte, which is as much in contact with the bottom of the tray above it as with the under one, which holds it. This permits of an equal chemical action upon the upper surface of one tray and the under side of the one above it.

In preparing the plates, the under side of each tray is chemically treated to become oxide, and the upper side per oxide of lead. This makes the upper side of each tray the positive side, and the under one the negative side, of what in other batteries would be a single cell.

The addition of another tray to the nest is simply the same as adding another cell to an ordinary battery. Of course, the bottom of the lower tray and the inside of the upper one are plain, and are not in contact with the electrolyte. A battery of 11 trays is practically the same as an ordinary one with 10 cells. The voltage of the battery will be twice the number of trays minus one.

One of the battery terminals, the positive, is attached to the bottom side of the bottom tray, and the other, the negative, to the top of the upper one. For the use of the entire battery, there is no connection between the trays except the electrolyte. The use of "jumpers" between the plates, as in ordinary batteries, being unnecessary.

Any combination of series-multiples or multiple series connections can be obtained that are possible with any battery. One terminal can be applied to the top of any tray of the nest, the other to the bottom of any other one. The voltage will always be twice as much as the difference between the number of trays. Between the top of the second tray and the bottom of the fourth one, the e. m. f. is 4 volts; the top of the third and the bottom of the ninth, 12 volts, etc.



SMITH STORAGE BATTERY.

One of the advantages claimed for this type of battery is its extremely low internal resistance. There are no lugs, soldered joints or loose connections, with connecting wires or strips from plate to plate, to offer resistance. At the latter part of a discharge, the current does not have to come from the bottom of the plate through the already discharged upper end. The discharge is practically continuous from the entire surface of every plate.

This results in another advantage, which is the rapid or uneven manner in which it can be discharged without fear of buckling. Inasmuch as the discharge is from the entire surface of all of the plates, it is claimed to make little difference whether it is accomplished in two or three hours or two or three days. Response is made to sudden changes of load with slight variation in voltage. This feature of even response to variable loads is of particular advantage for automobiles, where the demand varies so suddenly.

The form of the battery is claimed to preclude possability of the deposit of active material to form a short circuit between the plates, as frequently happens with jar batteries; such deposits come from the positive plates. In these batteries the positive face of the tray is up, so that there is no tendency for loosening of material; and, should that happen, it simply rests in the bottom of the tray, where it can cause no trouble.

Dispensing with all jars, either of glass or hard rubber, decreases the weight of the battery considerably, and reduces the cost. It is possible to nest an entire battery of any number of cells up to 20 or more.

*[To be continued.]*

## Personal.

Prof. F. Haber sailed for Europe on December 13th. On his extended trip through the United States, he visited nearly all the important electrochemical plants of this country. He intends to publish a report in the *Monographieen fuer Angewandte Elektrochemie*. He expects to issue this report in three or four months. In a recent letter to the president of the American Electrochemical Society, Dr. Haber expresses his sincere thanks for the very amiable reception tendered to him, and extends his hearty wishes for the future welfare of the Society.

## DIGEST OF U. S. PATENTS PRIOR TO JULY, 1902.

*Compiled by Byrnes & Townsend, Patent Lawyers, National Union Building, Washington, D. C.*

*This digest of electrochemical United States patents prior to July, 1902, will be one by classes, setting out for comparison in each class those devices which have the same object, or those methods which seek the same results. In each class the patents will be arranged chronologically. The digest will be complete in the sense of covering every point which is touched upon in the original specification.*

### DIAPHRAGM CELLS FOR THE PRODUCTION OF CAUSTIC ALKALI.

(*Continued from page 114*)

489,990. October 25, 1892; Henry Blackman, New York, N. Y.

Utilizes difference in specific gravities of brine saturated with chlorine and caustic soda solution, to maintain anode and cathode products of brine separate, by electrolyzing in a centrifugal apparatus, such as a revolving iron drum. Inner surface of drum partially protected by insulating coating, leaving cathode surface at greater distance from axis of drum than are the anodes, which may be arranged in a ring. Separate partitions to direct caustic soda, hydrogen and chlorine to suitable outlets. Central feed pipe for brine. Armature of dynamo to furnish current may be carried on same shaft as centrifugal electrolytic cell.

487,996. December 13, 1892; Thomas Craney, Bay City, Mich.

Closed iron vessel, serving as cathode, containing a number of anode compartments or porous cups. Each cup consists of a number of superposed, loosely interlocking, conical rings of stoneware or glass. A central anode in each cup, also consisting of a series of smaller superposed, conical cups, the space within the cups and the interstices between them being filled with pulverized carbon. Space between anode and porous cup filled with salt crystals, which gradually dissolve and replenish the solution.

488,708. December 27, 1892; Thomas Craney, Bay City, Mich.

Long anode and cathode compartments side by side, partially separated by a depending partition. A layer of sand or asbestos on the bottom of both compartments extends up above lower edge of the partition. A row of anodes, each consisting of a cup filled with pulverized carbon and resting on the sand layer. Connection to the carbon in each cup made by a tube filled with carbon. Cathode compartment divided longitudinally by a series of transverse vertical cathode plates, serving as baffles, causing movement of solution in a vertical zig-zag from end to end. Resistance between each anode and main electrical conductor arranged to increase current supply from inlet to outlet of cell.

489,677. January 10, 1893; James Greenwood, London, Eng.

Vessel of copper, lined with carbon or iron, serving as cathode. Anode, parallel plates of retort carbon, tinned on adjacent faces, with type metal cast between. Diaphragm, superposed V-shaped troughs of porcelain or glass, separated by asbestos or powdered steatite. Upward circulation of brine in both compartments. Anode and cathode solutions may flow through a number of cells in series.

491,700. February 14, 1893; Elisha B. Cutten, New York, N. Y.

Apparatus similar to that of 489,491, except that a porous cup may be substituted for glass anode bell. Upper and lower ends of porous cup glazed. Circulates strong brine upward along anode.

496,863. May 9, 1893; Thomas Craney, Bay City, Mich.

Apparatus similar to that of 487,996. Tank suspended from above and has conical bottom, delivering to a receiver below. Automatic device, controlled by strength of caustic, to regulate outflow from receiver.

496,864. May 9, 1893; Thomas Craney, Bay City, Mich.

Apparatus similar to that of 488,708. Modification shown employing a row of anode bells dipping into a layer of sand, with a cathode between each pair of bells.

496,865. May 9, 1893; Thomas Craney, Bay City, Mich.

Vessel partially divided into anode and cathode compartments by a depending partition. Sand layer on bottom extends up above lower edge of partition. Anode, solid or powdered carbon resting on sand at base of anode compartment. Anode conductor, a tube perforated at its upper end and filled with carbon. Cathode, a loosely-rolled sheet of metal.

498,768, 498,769, 498,770. June 6, 1893; Thomas Craney, Bay City, Mich.

A row of cells similar to that of 496,865, with all the anode and all the cathode compartments connected in series. Cells may be arranged in steps.

498,771. June 6, 1893; Thomas Craney, Bay City, Mich.

Porous cup, consisting of concentric perforated cups, with an intermediate space filled with asbestos. Inner cup filled with granular carbon, serving as anode.

501,121. July 11, 1893; Charles N. Waite, Newton, Mass.

Purifies brine by adding a soluble barium salt, preferably chloride, to remove sulphuric acid existing in combination with calcium, magnesium or sodium.

501,628. July 18, 1893; James Charles Richardson, London, England.

Cathode, a horizontal endless belt of sheet metal, supported on rollers near the bottom of vessel. Terminal brush bears on cathode. Feeds a depolarizer, such as copper oxide, onto one end of the cathode, and delivers the spent depolarizer from the other end into a receptacle, from which it is elevated. Anode bell arranged with its lower edge in contact with layer of depolarizer on cathode.

504,774. September 12, 1893; Thomas Craney, Bay City, Mich.

Separate anode and cathode compartments, connected by an inverted U-tube filled with asbestos. Anode and cathode similar to those of 496,865. Fills cathode compartment with water or weak brine, and displaces caustic by adding fresh water.

505,895. October 3, 1893; Elisha B. Butten, New York, N. Y.

Apparatus similar to that of 489,491 and 491,700. Automatic devices for supplying saturated brine and withdrawing caustic.

507,886. October 31, 1893; Thomas Craney, Bay City, Mich.

Separate, parallel, rectangular anode and cathode compartments of iron. Anode compartment protected by coating of asphalt and an inner lining of cement. A series of inverted U-tubes connect the compartments. End of each U-tube in anode compartment may rest on a pile of asbestos sheets. An air exhaust pipe leads from the bend of each U-tube. Anode, a layer of pulverized carbon resting on bottom of compartment, with a series of connections, each a carbon pencil encased in earthenware or cement. May have an anode compartment along each side of cathode compartment.

## ALUMINIUM.

In this issue we publish three articles on the manufacture, the properties and the uses of aluminium. In 1854, Prof. Deville, of Paris, succeeded in obtaining metallic aluminium by electrolyzing the fused double-chloride of aluminium and sodium. In those days, however, electrical energy was expensive, as primary batteries were then the only means of generating an electric current; and Prof. Deville concluded that the electrolytic method could not compete with purely chemical methods. It is amusing to note how completely the situation is now changed, since electrical energy became cheaper and the processes of Hall and Heroult were introduced into practice on a large scale. The article by Dr. J. W. Richards, who has been intimately connected with the development of the aluminium industry, will engage the attention of our readers, as it gives interesting historical notes on the work of Hall and Heroult, together with a discussion of the scientific principles of their process.

Prof. C. F. Burgess and Mr. Carl Hambuechen give an account of valuable laboratory observations on aluminium. To utilize aluminium to greatest advantage, one must be familiar with its particular properties, and especially with its almost ever-present surface coating. The authors show how this coating introduces peculiar difficulties in various processes, like soldering aluminium, plating on aluminium, etc., and they also show the means of overcoming these difficulties. Electroplating upon aluminium should have a great commercial field for certain utensils. On the other hand, the problem of plating with aluminium seems to resolve itself into the problem of finding a suitable solvent which will dissolve an aluminium salt and at the same time will not chemically react with the deposited metallic aluminium. It seems certain that water as a solvent does not do.

The third article in this issue on aluminium is by Mr. G. P. Scholl, on the use of aluminium as a reducing agent in metallurgical processes. That aluminium is a very strong reducing agent has long been known, but there was no use of working out the details of such a process, as long as aluminium itself was expensive. The decrease of the price of aluminium paved the way for Dr. Goldschmidt's important process. In this connection we may note that calcium carbide has similarly been tried as a reducing agent in recent years. These are only special cases of the general rule that electrochemical processes enable us to store up energy in producing chemicals which may afterwards be used as reagent in other processes.

## ON FARADAY'S LAW.

In this issue we print two contributions relating to Faraday's law; a long article by Mr. Carl Hering, and a brief communication by Dr. H. C. Cooper. Dr. Cooper refers to an

article published in our November issue on Faraday's law and the theory of electrons. In this article it was shown that Prof. O. C. Johnson's well known notation of positive and negative bonds may easily be applied to electrochemical calculations, because his positive and negative bonds may be considered to correspond to positive and negative charges. In electrochemical processes the change of valency in Johnson's sense is nothing else but the giving off or receiving of electric charges at the electrodes. Prof. Johnson's old notation may therefore be interpreted as an expression in different words of what is now generally assumed to be the mechanism of the transport of electricity through an electrolyte by means of charged ions.

Dr Cooper appears to consider it preferable for didactic reasons to put the latter mental picture at the head of such considerations. He appears to object to the use of the word bond. But whatever may be thought about bonds and valency in the light of recent investigations, we do not see any possible way to evade the idea of valency in electrochemical action and in the application of Faraday's law. It does not seem possible to describe the chemical action at the electrodes of an electrochemical cell otherwise than as reduction and oxidation (or as Dr. J. W. Richards says, "perduction"), that is, as changes of valencies. Of course, one might use other terms, but we do not see what useful purpose could thereby be accomplished. Even Dr. Cooper, after having expressed himself against the use of the terms bond and valency, uses, in the expression of Faraday's law, the term "equivalent amounts." With the essential contents of Dr. Cooper's explanations we fully agree; in fact, he states the views expressed in our former article on Faraday's law and the theory of electrons, only in different words, by carefully evading the term chemical bond and substituting for it at once the idea of an electric charge. This is in absolute agreement with the sentiment expressed in our former article.

Mr. Carl Hering's article will certainly be extremely welcome to the rapidly increasing number of workers in the electrochemical field. Faraday's law is the foundation of every calculation in electrolytic processes, and a table which simplifies these calculations and saves time is, of course, of great value to the busy practical man. The table is also to be heartily recommended as being the result of a complete and careful recalculation of the electrochemical equivalents, based upon the most recent and best fundamental values; moreover it contains columns relating to the energy, which we believe are not to be found in any other table and which may often be used to advantage in practice.

In the text which accompanies his table, Mr. Hering illustrates the use of his table by a series of typical examples, well chosen, in order to show the great variety of possible cases. This text is, in fact, a concise treatise on Faraday's law, and the student who reads it carefully and recalculates the various examples should be highly benefited. We desire to add a few remarks on the relation between the methods of calculation, described by Mr. Hering and that in which the ionic charge is used as a basis; and some further remarks on the interconnection between the two methods, described by Mr. Hering.

The method of calculation, which is based on the ionic charge, is perhaps the safest for anyone familiar with the idea of charged ions in all but the simplest cases. The method is to first find the equation which represents the complete electrochemical action; this action is necessarily a reduction at the cathode and a "perduction" (or oxidation) at the anode. In the sense of the ionic theory the reduction at the cathode is a loss of positive charges given off to the cathode; monovalent ions (like H) give off one charge; bivalent (like Cu in $CuSO_4$) two charges, etc. The perduction at the anode is a gain of positive charges (or a loss of negative charges); the zinc atom which goes into solution in the Daniell cell is changed from an atom to an ion and thus gains two charges. It is evident that the number of charges received from the anode in any given time must be exactly equal to the number of charges given off to the cathode in that time. When the equation representing the whole reaction has thus been found, and when it has been determined how many charges are received from the anode and given off to the cathode, then one has simply to remember that each such charge represents 96,540 coulombs, if the chemical symbols in the equation represent gram molecules or gram atoms or gram ions. The further calculation is then very simple. There is no essential difference between this method and the method based upon the change of valency in connection with the table, but there is this practical difference: the former method requires some calculations which are avoided by the use of the table.

One point might, however, be emphasized. While the valency is generally considered in text-books to be the determining factor in calculations with reference to Faraday's law, Mr. Hering speaks of the *change of valency*, instead of the valency itself. This is strictly correct, and the ionic theory takes exactly the same view. For instance, if at an inert cathode ferric sulphate is reduced to ferrous sulphate, the change of valency of Fe is from three to two, the difference being one. From the point of view of the ionic theory, a three-valent Fe gram ion has a charge of three times 96,540 coulombs and a bi-valent Fe gram ion has a charge of two times 96,540 coulombs; hence the change from a three-valent to a bi-valent gram ion Fe corresponds to giving off 96,540 coulombs to the cathode.

Finally we will point out the interconnection between the two methods, discussed in Mr. Hering's article. The one consists in taking the change of valency and reading the amount perduced at the anode or reduced at the cathode directly from the table. The other method, which he calls the older chemical method, requires the exact knowledge of the equation representing the total electrochemical action. It is, of course, self-evident that both methods must be essentially one and the same, but there is one point which, at first sight, may appear a puzzle to the student. In "the older chemical method" one must know the co-efficients of the different terms entering into the equation of the electrochemical reaction. In the other method nothing is required but a knowledge of the change of the valency, and Mr. Hering even gives an example to show that the co-efficients in the equation of the reaction may be ignored. It is self-evident that this puzzle can be solved only by proving that there is a distinct relation between

the co-efficients of the equation and the numbers representing the change of valency at both electrodes.

Now this relation is nothing but the old well-known rule given by Prof. O. C. Johnson for balancing an equation which represents a process involving oxidation and reduction. This means that if we know the change of valency of the element reduced at the cathode (for instance, say, three) and the change of valency of the element perduced at the anode (say two), then we know the co-efficients with which these elements enter into the equation representing the total electrochemical reaction. In our special case this co-efficient is two for the former (reduced) element and three for the latter (perduced) element. As was pointed out in the article in our November issue, already referred to above, this rule becomes quite self-evident in the light of the ionic theory. In our special case it means that if the element reduced at the cathode gives off three positive charges to the cathode and the element perduced at the anode receives two positive charges from the anode, then it is necessary that two atoms are reduced at the cathode in the same time as three atoms are perduced at the anode, because only under this condition the same number of positive charges (six in this special case) pass from the anode into the electrolyte as pass from the electrolyte to the cathode.

## PHYSICAL CHEMISTRY AND ELECTROCHEMISTRY.

In a recently published report of the Census Committee of the American Chemical Society, Dr. Louis Kahlenberg discusses the development of modern physical chemistry. He points out that it would be wrong to believe that physical chemistry has sprung up suddenly and has developed from the subjects of chemistry and physics in an unnatural or artificial manner; on the contrary, the very opposite is shown to be the fact, as the beginnings of physical chemistry date back to the very beginnings of chemistry. The founders of modern chemistry, the men that were so prominent during the latter part of the eighteenth and the former part of the nineteenth century, to a very large extent employed physical means to investigate chemical problems. And during the period of the development of analytical and organic chemistry, while attention was primarily directed to the end products of chemical reactions, yet nearly all of the physical means known to-day were used more or less extensively; the balance, the pycnometer, the thermometer, the retort, etc., and even the calorimeter, the spectroscope, the polariscope, the galvanometer, the refractometer and photometer were at times called into requisition.

Dr. Kahlenberg shows how the two sciences of physics and chemistry, at first practically one, became gradually more and more distinct, as the chemists were chiefly occupied in studying the end products of chemical reactions, while the physicists developed refined methods of exact measurement. And yet during this entire period there always were some men whose researches lay on the border line between the two sciences. The work of these men kept alive the intimate connection between chemistry and physics and forms the foundation of modern physical chemistry. Modern physical chemistry is distinguished from the older "pure" chemistry, not by the methods used, but by the object of investigation; the field is a broader one. Not only the end products of chemical action are studied, but also the processes of the formation of these products, together with all the concomitant energy changes that take place. Physical chemistry is thus general chemistry—chemistry of the most general kind. Dr. Kahlenberg concludes his remarks by appealing to physical chemists to bear constantly in mind the general aim of their work, which, like that of all sciences, is to minister to the welfare of mankind in the broadest and highest sense of the word. Science must have all avenues for its progress open; but it must be borne in mind that science is for man and not man for science.

We call attention to these remarks of Dr. Kahlenberg on the development and the aim of physical chemistry, because we want to make some similar remarks on electrochemistry. Electrochemistry is often spoken of as the youngest branch of electrical engineering. This is correct as far as the industrial success is concerned. On the other hand, it should not be forgotten that electrochemistry is as old as electrical engineering. When Volta deviced in 1800 a cell by which chemical energy was changed into electrical energy, he was an electrochemist; and in 1807 Davy isolated the elements potassium and sodium by electrolysis of fused caustic soda and caustic potash and thus succeeded in bringing about new chemical reactions by means of the electric current. True, there was afterwards a long period in which industrial electrochemistry made practically no headway; but during this period, beginning with Faraday, the foundations were laid of modern theoretical electrochemistry.

It is out of place to sketch here the splendid development in recent years of industrial electrochemistry. The progress has been rapid and the success sweeping and the outlook for the future is very bright, especially as it becomes more evident every day that electrochemistry is only in the beginning of its industrial development, especially in this country with its enormous resources. The progress in future promises to continue to be rapid, but in order to be healthy, progress must be made on conservative lines. Industrial electrochemistry must remain in touch with theoretical electrochemistry and physical chemistry in general. It is a very good symptom—which was manifest to every one who attended the first two meetings of the American Electrochemical Society—that there is in this country good will and good feeling between electrochemical engineers and scientists, that both classes of electrochemical workers feel that they must stay together.

Electrochemistry is only a special branch of physical chemistry. Electrochemical scientists must be allowed to push forward on any road that seems to promise success. The roots of electrochemical science are in general physics and chemistry, and no progress in these sciences is so remote from the subject of electrochemistry that it should not be carefully watched by electrochemists. There is no pure science which cannot be eventually applied to the welfare of mankind. The practical man should not despise theories which at first seem to be "of scientific interest" only; and the theorist should never forget that as Dr. Kahlenberg puts it, science is for man, not man for science.

## THE CASTNER MEMORIAL TABLET.

A distinguished audience attended the ceremonies of the unveiling of the beautiful bronze tablet in Havemeyer Hall, School of Mines, Columbia University, at 4 o'clock, on Tuesday afternoon, December 10, 1902. Addresses were delivered in the large chemical lecture room by Dr. Chas. F. Chandler, dean of the School of Mines and the professor under whom Mr Castner studied chemistry for three years; by Dr. Marcus Benjamin, of the United States National Museum at Washington, who, as a classmate of Mr. Castner, related some personal reminiscences illustrating his characteristics as a student and investigator, and by Prof. Joseph W. Richards, of Lehigh

University, representing the American Electrochemical Society. Dr. Chandler related the history of the inception and development of Mr. Castner's inventions, while Dr. Richards discussed more particularly the relation of Castner's work to the aluminum industry, the general question of his pioneer work in electrochemistry and the effect of his inventions on industrial and economic progress. The audience then filed into the corridor, where, in the presence of Mrs. Castner and the company which had gathered to do her husband honor, Dr. Chandler, after a few impressive and appropriate words of dedication, drew aside the curtain.

## ELECTROLYTIC PROCESSES.

In his presidential address delivered before the (British) Institution of Electrical Engineers, Mr. James Swinburne makes some very interesting remarks on electrolytic processes.

"This [electrolysis] is a branch of industry in which it is very difficult to tell our limits. In electrolytic copper-refining our limit is that of the copper wanted. Our electrolytic industries suffer mostly from the limits of intelligence of the investing public. It is assumed that we cannot do electrolysis in England because we have no water-power. This is only an excuse for inactivity. As already* explained, we can do just as well without water-power. A blast furnace is much more valuable than a waterfall of similar power, because it is near coal and in an industrial district. Moreover, as already explained, the cost of electrical energy is a small portion of that of most electrolytic products. At first electrolysis was to be applied to copper refining, then to caustic soda.

"The output of electrolytic caustic is really rather limited by the demand for bleach. What is urgently wanted is some other way of storing and carrying chlorine. Steel bottles and compression plant are an unsatisfactory solution. What are the limits in the way of electrolyzing fused salt? They are all incidental limits. The containing vessel is a difficulty. Sodium vapor attacks all silicates. Sodium distills near the temperature of fused salt. If not volatilized it forms a conducting bridge from the cathode. It attacks iron, though slowly. Hot porcelain and earthenware conduct electrolytically—as, by the way, the maker of electric frying pans knows—hot chlorine attacks metals, even when dry, and hot carbon cannot be exposed to the air. In addition, sodium, and perhaps chlorine, are soluble on hot salt, and traces of sulphate in the salt act as carriers, as sulphate and sulphide. I could a tale unfold if I read out laboratory notes of sodium experiments on a large scale. The difficulties are all incidental though, and I have little doubt electrolytic sodium at a low price will be in the market soon, and will affect profoundly many chemical and metallurgical industries. I would like an opportunity to continue experiments myself, but others will, I feel certain, soon succeed.

"In metallurgy electrolytic solution processes are in use or on trial for the more valuable metals, such as copper and nickel. The reaction between chlorine and metallic sulphides at high temperatures brings the whole domain of sulphide ores under our sway. Thus a sulphide, say galena, is treated with chlorine, which gives off the sulphur, as sulphur which is condensed and sold, making chloride of lead. The silver is extracted by stirring with a little lead, and the fused salt is then electrolyzed, yielding pure desilverized lead and chlorine. The process is thus self-contained, yielding sulphur, lead and silver. It is specially applicable to mixed refactory ores which are now nearly valueless and very plentiful, and contain much metal content, such as the mixed lead-zinc sulphides of America or Australia. These reactions have been proved on the large or ton scale, and there is no technical difficulty. Unfortunately mine people are somewhat ignorant of electrical matters, and it is exceedingly difficult to get them to understand or appreciate a process like this, capable though it may be of paying good dividends on very large capitals indeed.

"In all these metallurgical extractions we may roughly take the cost of energy as a farthing per kilowatt hour for steam, and half that for gas. Allowing a rough average pressure per cell, we may take it that electric energy costs $500 per ton, or ton equivalent by steam, and $250 by gas. That would be $15 a ton for zinc, $5 for lead, $15 for copper and iron by steam, and half these figures by gas-power. This means that the metallurgy of all sulphides, except, perhaps, iron, is within our grasp. It may pay to make a pure iron, free from phosphorus, silicon, manganese and carbon at something under $50 a ton from pyrites ores (which may also contain zinc, nickel, copper, etc.), and then, add exactly the desired amount of other constituents or 'physic' to produce with accuracy steels of special grades.

"But our limit in electrolysis in this country [England] is almost entirely human inertia. Commercial and financial people do not understand it, and fight shy of it. But our technical people are nearly as bad. The pure physicist, as a rule, takes no interest in electrolysis or physical chemistry, and thinks it belongs to the chemical class room on the other side of the passage. The chemist thinks it is higher mathematics, and will have none of it; the mathematician thinks it may be an exercise in differential equations; but they are all agreed that it is a sort of continental fungus which flourishes with no roots, and that it is beneath the attention of a scientific man to know enough about it to give a reason for the broad statement that it is all nonsense."

* See *Electrochemical Industry*, Dec., 1902, vol I page 118.

## ELECTROLYTIC REFINING OF GOLD.

By D. K. TUTTLE, PH.D.
Melter and Refiner, U. S. Mint, Philadelphia.

The problem of refining silver containing small amounts of gold, and other impurities, by electrolysis has been solved, and the industrial establishments of to-day treat practically the entire silver product of our mines in this manner.

Only the gold residues reach the mints. Indeed, the scarcity of silver deposits at the Government institutions has been a serious inconvenience, since the usual acid refining methods require a large amount of that metal as parting material in treating the gold bullion received.

The great mass of gold deposits contain some silver and are usually too impure for either coinage or industrial use without refining. Some contain platinum, which is lost in the usual wet processes.

It has been the practice to alloy the gold in the deposits with 2½ times its weight of silver, and subject this mixture to the action of nitric or sulphuric acid. In consequence of the very limited deposits of silver, it is necessary to use the same silver repeatedly as parting material, at a great expense for acid. If 2½ times as much impure silver as of gold came to the mints, the parting processes would not be so wasteful.

The only process for directly refining gold electrolytically that is known to have been reduced to practice is that patented by Dr. Emil Wohlwill, Hamburg, Germany, United States patents 625,863 and 625,864.

The feature protected by patent is the electrolyte. This is composed of gold chloride solution rather strongly impregnated with free hydrochloric acid, and it is in this latter point that the significance of the invention lies. If a gold anode is placed in a neutral or only slightly acid solution of gold chloride, opposed by a suitable cathode, gold will be deposited by an electric current, but little or no gold will be dissolved from the anode. Free chlorine is given off, a result not to have been anticipated since chlorine is an active solvent for gold. Upon the addition of free hydrochloric acid to the bath, a point is reached where the chlorine at the anode is suppressed, and gold passes into solution, equivalent for equivalent, to that deposited. The strength of the electrolyte is easily maintained by such additions of gold chloride from time to time as will be equivalent to the copper, platinum, etc., dissolved from the anode, and not deposited on the cathode. The operation is continuous until the solution becomes highly charged with impurities.

The Wohlwill process is in use in the two great refineries of Germany—the Norddeutsche at Hamburg and that at Frankfurt (formerly Dr. Rössler). In a private letter to the writer, Dr. Wohlwill states that gold has been refined by electrolysis in the Hamburg plant since 1878, uninterruptedly, and that now practically all the gold refining done in Germany is effected by this method.

Correspondence with the patentee resulted in the purchase of a right to use the Wohlwill patent in the mint at Philadelphia, and a plant has been introduced which is being gradually enlarged.

### PROCESS.

The apparatus consists of first: A dynamo, which, when run at its normal capacity, requires 5 horse-power and furnishes a current of 600 amperes at 6 volts. The machine having been designed with a view to experimental work, a rheostat in the field-winding enables us to regulate the current between 100 and 600 amperes.

ELECTROLYTIC REFINING ROOM, U. S. MINT, PHILADELPHIA.

Second: The cells, which are of white porcelain (Berlin ware), are 15 inches long x 11 inches wide and 8 inches deep. These are filled with a prepared solution of gold tri-chloride containing 30 grammes of gold per litre (3 8-10 Troy ounces per gallon), the depth of the solution being such as not to entirely submerge the anodes. In each of these cells are suspended 12 anodes and 13 cathodes, *in multiple*. The anodes are each 6 inches in length, 3 inches wide and ¾ inch thick. The corresponding cathodes are of fine gold and rolled down to 1/100 of an inch in thickness. The distance between anode and cathode is 1½ inches. In our present working seven cells are placed end to end on a bed of sand underlying which is a series of steam pipes by which the temperature of the bath may be raised and maintained at any desired degree. At present our cells are kept at from 50° to 55° C. The increased temperature serves to reduce the voltage required, and at the same time to diminish the amount of free acid necessary to suppress evolution of chlorine at the anodes.

Circulation of the electrolyte by mechanical means is necessary to secure uniform disintegration of the anode and deposition of the gold.

The seven cells in use are connected up, *in series*, with the dynamo, which is at present regulated to furnish 100 ampères. The tension between the terminals of the seven cells varies from 4½ to 5 volts, dependent upon temperature, strength of solution, etc.

The chemical equivalent of gold is very high, and the electromotive force required for the deposition of gold is very low, so that the power necessary for running the plant is insignificant. With only seven cells of our plant in operation, we are refining about 5,000 ounces per week, with the expenditure of about 1 horse-power. One attendant suffices to manage the work, with the occasional assistance of a second workman.

The cost for hydrochloric acid in the bath is 20 cents per 1,000 ounces of deposited gold.

We can increase our refining capacity to 50,000 ounces per week with our present plant.

Beside the advantage the process offers for the refining of gold with an insignificant consumption of acid, with little labor, and small expenditure of power, an important one should be mentioned, viz., the recovery of any platinum present in the bullion. This dissolves, but is not deposited with the gold. When the electrolyte becomes sufficiently charged with platinum, the gold is first precipitated by sulphur dioxide, and removed. Then the platinum remaining in solution is separated as ammonium platinum chloride. Lastly, the copper is recovered by passing the wash waters over iron scrap.

With these advantages to its credit, the process has limitations which are serious ones. Any silver in the anodes will, of course, be converted into insoluble chloride, and if the percentage be small will fall to the bottom of the containing tank as "slimes." But if the amount of silver exceed 5 per cent. the chloride tends to adhere to the anode, as a crust, which must be mechanically removed.

Furthermore, any considerable quantity of copper present in the bullion to be treated is undesirable, since the electrolyte, in that case, must be renewed inconveniently often.

There seems to be reason to think that any electrolytic process for parting and refining gold will not have the same success in this country in our industrial plants as it met in Europe. The Australian, South African and Hong Kong native gold is very much purer than even our California nuggets, and they were very much better than our recent finds in Alaska.

Hong Kong gold is reported as containing .975 gold, .020 silver, .0005 platinum, .0005 iridium.

Some recent consignments of Klondike gold to this mint varied from .776 gold to .834 gold, .219 silver to .101 silver, with no showing of platinum or iridium in the electrolyte.

Such bullion can only be successfully treated by the "Wohlwill" process when blended with a higher-grade gold. We prefer not to treat bullion having a fineness of less than .940 gold.

Again, the Government conditions for the gold producer here are much more favorable than in other countries. At any United States mint or assay office the depositor is entitled to receive promptly upon assay of his bullion all the gold it contains in the form of gold coin or draft on the treasury, less some slight charges. If the amount of the deposit be large he may even receive an advance of 80 per cent. on its approximate value at the time of making the deposit. Under these circumstances the question of *interest* becomes an important item with the industrial establishments. With a given output per diem, several times the value will be locked up in solution, anodes, cathodes and material in various stages of leaching, melting, etc.

It is to be feared that with the liberal system in vogue in this country, the depositor will still find it to his advantage to deliver to the Government high-grade, but not very pure, bullion for spot cash, pay the slight charges and leave the melter and refiner to wrestle with the refining.

For the patrons of the United States mint, however, the "Wohlwill" process has been a great boon. The gold bars furnished have been exceptionaly high (999.8), and this grade is especially sought by makers of dental gold and leaf. Under slight pressure it coheres and compacts into a reguline mass, as perfect as if melted and poured in a mould. A medallion head of Washington was made from spongy electrolytic gold by simple pressure in the die press, and the result was a perfect success, too soft for wear, but a beautiful medal.

This especially high-grade gold is being distributed to appreciative customers at many points distant from Philadelphia.

---

## THE PRESENT METALLURGY OF ALUMINIUM.

By Joseph W. Richards, Ph.D.

*President of the American Electrochemical Society.*

THE aluminium now being manufactured is being made by one process only, viz., the electrolysis of alumina dissolved in a bath of melted aluminium-sodium double fluoride. The principle involved in this process was discovered by Paul L. V. Héroult, in France, and Charles M. Hall, in the United States, in 1886. The principle is easily understood when once known; it is, that the melted double fluorides of aluminium and more electropositive metals can dissolve a considerable proportion of their weight of the relatively infusible alumina, and that when such a solution is electrolyzed, aluminium and oxygen appear at the two electrodes until the dissolved alumina has been almost entirely eliminated; and that, by the addition of fresh alumina the process can be made continuous, while the solvent bath material remains unaffected by the operation.

Before describing the efforts of Hall and Héroult, it may be well to say that the process is the invention of these two investigators alone, and the hysterical attempts of Mr. A. Minet to claim a share in the discovery and application of this principle, especially his temerity in calling the present process the Minet Hall process, are without the slightest basis or justification in actual fact. In a recent German monograph, Mr. Minet devotes 19 *lines* to the original patent of Mr. Héroult (by which some 3,000 tons of aluminium is manufactured yearly), 32 *lines* to the patents of Hall (by which some 6,000 tons is made yearly), and *20 pages* to the description of Minet's process, by which not a pound is being commercially manufactured, nor is it at all likely to be. Hall's and Héroult's processes were discovered, and patents applied for, in 1886; Minet himself dates his first experiments from February, 1887. Minet makes a bath of 60 parts sodium chloride and 40 parts aluminium-sodium chloride or fluoride, and electrolyses this bath, producing therefrom aluminium and chlorine, or perhaps, fluorine, and regenerates the bath by piling alumina around the anode where, by the simultaneous contact with the carbon anode and the gaseous halogen, it is partly decomposed and enters the bath as aluminium fluoride. Such, at least, is what Mr. Minet says happened to his bath; but, however that may be, no sodium chloride is used at all in the present process of manufacture, and while Minet may make a Quixotic claim that the present is the Minet-Hall process, no court would sustain his claim, particularly since he only began his experiments the year *after* Hall and Héroult had applied for their patents.

Turning now to the Héroult process, it was first conceived by him in 1886. At the Metallurgical Congress at Paris, in 1900, Héroult described how he stumbled across it. He was attempting to electrolyze melted cryolite, the native double fluoride of aluminium and sodium, $AlF_3.3NaF$, with an iron cathode and carbon anode, and adding some double chloride of aluminium and sodium, $AlCl_3.2NaCl$, to the melt to make it more easily fusible. He obtained aluminium alloyed with his iron cathode, but no evolution of either chlorine or fluorine at the anode, yet the anode was attacked and evolved a gas. He concluded that some oxide had gotten into the bath, whose

oxygen was attacking his anode. He took up this clue, and on testing the aluminium-sodium double chloride which he had used, found that it had been largely converted into alumina by the moisture of the air, and thus alumina had gotten accidentally into the bath. On adding pure alumina, later, he found that this explained the question, and that the electrolysis produced only aluminium and carbonic oxide.

Héroult was then a student, twenty-three years old, and after taking out his patent in France in April 23, 1886, number 175,711, he went for advice to the established manufacturer of aluminium by the sodium process—Pechiney at Salindres. Here he was advised that the uses of pure aluminium were so limited that his process was of little value, and that if he would put his attention on producing cheaply the alloys of aluminium and copper or iron he would start a much greater industry. He accordingly set to work on his idea of electrolyzing pure alumina melted alone in the electric furnace, using a copper or iron cathode, and in 1887 took out additional patents for this alloy process. Going thence to Switzerland, he worked for a year at the Rhine Falls, producing only aluminum alloys, such as the bronze, by this alloy process. Finding in 1888 that Hall, in America, was producing commercially pure aluminium by a process analogous in principle to his original patent, Héroult resurrected his earlier pure-metal process and, with the aid of Dr. Kiliani, set to work making pure aluminium, which he placed upon the market only some twelve months after Hall in America had commenced operations on a commercial scale.

The process of Heroult, patented in 1886, describes putting alumina into a carbon crucible, and adding cryolite in sufficient quantity to render it fluid at a moderate heat. The crucible itself serves as cathode while a carbon anode dips into the bath. The crucible is placed inside a larger graphite crucible, and the space between the two filled with graphite, into which dips the negative carbon. A cover having holes for the insertion of the conducting carbons is provided, and a layer of clay or loam put on top to exclude air and gases. Héroult stated that a current of three volts was sufficient to produce decomposition, but that a convenient strength of current for a crucible 20 centimeters deep by 14 centimeters inside diameter, with a carbon anode 5 centimeters in diameter, was 400 amperes, which required a potential of 20 to 25 volts. The crucibles were placed in a wind furnace and kept hot by a fire, during the electrolysis. The idea of a continuous operation by adding fresh alumina is conspicuous for its absence in this description, as all the arrangements point to the idea of running a charge in the crucible, tightly closed, then lifting it out of the furnace, removing the luting and covers, and removing the contents of the crucible.

The probabilities are that Héroult did not make more than a few ounces of metal in this way until 1889, when, hearing of the success of Hall in America, he started, with Dr. Kiliani's assistance, to develop his process into commercial shape, and it was not until September, 1890, that his company was selling pure aluminium.

How the process has been developed abroad we know only by the results. Dr. Kiliani patented a revolving furnace, with a movable anode, but this has been abandoned. The European Works, operating under Héroult's patent, are not open to the public, and no details of their working are given by the managers. It is the writer's opinion that the method of working adopted in these works is practically that used by Hall in America since 1888, and that the great secrecy of the European makers is used principally to avoid it being known how closely they have copied the American style of apparatus. This opinion may be wrong, but it explains the situation so well that it commends itself as the true reason of their secrecy.

The plants working with licenses under the Héroult patents are the Aluminium-Industrie-Aktien-Gesellschaft, at Neuhausen, Switzerland, 4,500 horse-power; at Rheinfelden, Baden, 5,000 horse-power, and at Lend-Gastein, near Salzburg, Austria, 3,000 horse power, also the Societe Electrometallurgique Française at La Praz, Savoy, 3,000 horse-power, and the British Aluminium Co., at Foyers, Scotland, 6,000 horse-power. Part of the power of all of these plants is used for making calcium carbide, and the proportion used for aluminium is not exactly known; it is probably not over 12,000 horse power in all of those plants put together, and possibly less.

Mr. C. M. Hall approached the subject from the standpoint of trying to find a fluid melted salt in which alumina would dissolve and out of which it could be electrolyzed. As he has several times explained to the writer, he had in mind the analogy to dissolving a salt, such as copper sulphate, in water, and obtaining the ingredients of the salt at the two electrodes without decomposition of the water. For this end, he experimented to find a melted salt which would (1) dissolve alumina freely, (2) conduct electricity, (3) yield only aluminium and oxygen on being electrolyzed, (4) not volatilize or deteriorate on continued use. After a long and arduous investigation, in which almost all the single and double salts of aluminium were tested, and many fusible salts of other metals, Mr. Hall discovered that the double fluorides of aluminium and the more electropositive metals were the only salts which possessed the above qualifications. The process was first operated in February, 1886, and patents applied for July 9th of the same year.

During this period, in May, 1886, Mr. Héroult, of France, had applied for a United States patent corresponding to his pure metal process, already described. The patent office instituted interference proceedings, with the result that it was found that Mr. Hall had made his invention and practised it before any publication of Mr. Héroult's process had been made, and was therefore, entitled to the United States patent. In consequence of this decision the patent in this country was issued only to Mr. Hall. Later, Heroult obtained United States patents for his alloy process, and the same was installed experimentally at Boonton, N. J., but it was not a commercial success.

Mr. Hall applied on July 9, 1886, for a single patent, which was issued on April 2, 1889, after division of the original application and re-application. The patents are numbered 400,664, 400,665, 400,666, 400,667 and 400,766. They cover variations of the original principle. For instance, Mr. Hall found that the double fluoride of aluminium and potassium or lithium was a very easily fusible salt, and possessed the required qualifications for use in his process, being of particularly low specific gravity. The cost of these salts is the particular item in which they are inferior to the corresponding sodium salt. Again, the double fluorides of aluminium and the alkaline earth metals are also effective, with the drawback of a high specific gravity, greater than that of aluminium, and therefore more suitable for producing alloys of aluminium than the pure metal.

Two of the broadest claims of Mr. Hall are as follows, from patent number 400,766:

"1. As an improvement in the art of manufacturing aluminium, the herein described process, which consists in dissolving alumina in a fused bath composed of the fluorides of aluminium and of a metal more electropositive than aluminium, and then passing an electric current through the fused mass, substantially as set forth.

"2. As an improvement in the art of manufacturing aluminium, the herein described process, which consists in dissolving alumina in a fused bath composed of the fluorides of aluminium and sodium, and then passing an electric current, by means of a carbonaceous anode, through the fused mass, substantially as set forth."

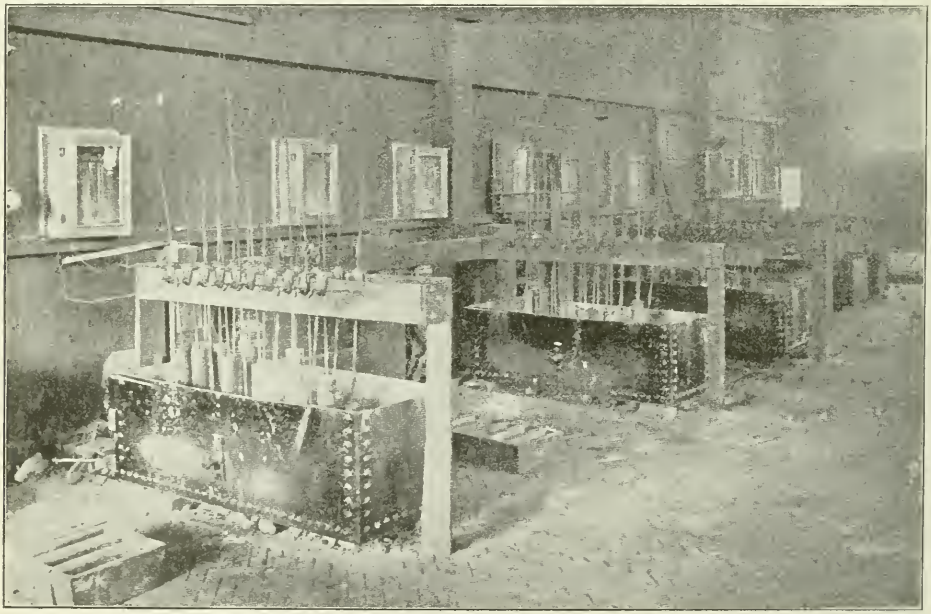
The other patents enumerated claim specifically the use of double fluoride of aluminium and potassium to form the bath, also of lithium fluoride in the bath in place of part of the sodium or potassium fluoride, also the use of calcium fluoride in the bath, and of the double fluorides of aluminium and

alkaline-earth metals. In patent 400,667 especial emphasis is laid on preserving the continuity of the operation by adding alumina as the bath becomes impoverished in alumina, and removing aluminium from the bath, by tapping or ladling out, without interrupting the process.

The Hall process first began commercial operations at Pittsburg, using 125 horse-power, in November, 1888, and producing 50 pounds per day. Since then, the history of the process is one of steady increase in size and efficiency. In place of small cast-iron pots, taking 1,800 ampères and requiring 8 volts to run them, and requiring over 2 horse-power to each pound of aluminium produced daily, there are now used large wrought-iron pots, taking 10,000 ampères and requiring but 5 to 6 volts each, and producing probably 1½ pounds of aluminium daily for each horse-power applied. In place of the 125 horse-power at Pittsburg, there is now in use 10,500 horse-power at Niagara Falls and 5,000 horse-power at Shawinegan Falls, Quebec.

The principle of the process, however, retains its original

All the impurities of the alumina used pass into the metal produced, and to obtain pure metal it is therefore absolutely necessary to use the purest alumina. This requirement has led to considerable improvement in the manufacture of alumina, the Baeyer process being in considerable use both here and abroad, while in addition to this, Mr. Hall has invented a lime-process of wet chemical treatment, which is installed on a large scale at East St. Louis and is producing alumina of the highest quality; he has also patented the method of purifying bauxite or crude alumina by mixing it with sufficient reducing agent to reduce the impurities present, and then melting down the mixture in an electric furnace. The result of the last process is a dense, granular purified alumina, in form and composition very suitable for reduction. The lime process is the subject of Hall's United States patent 653,167 of December 4, 1900; while the electric-furnace method of purification is in United States patents 677,208 and 677,209 of June 25, 1901, and 706,553 of August 12, 1902. The Pittsburg Reduction Co., operating the Hall process, also bakes its own carbon elec-



A HALL ALUMINIUM BATH.

simplicity. The bath material consists of the double fluoride of aluminium and sodium; alumina is dissolved in this up to a maximum of 15 to 20 per cent. As the alumina is removed by electrolysis and the resistance of the bath goes up, fresh alumina is stirred in. The 3-inch carbons used carry each 250 ampères of current, and are kept at approximately an inch from the negative electrode, which is the melted metal in the bottom of the pot. The large size of the pot and correspondingly heavy ampèrage passing through develops enough heat in the electrolyte to keep the contents melted without the assistance of exterior heating, which is thus rendered unnecessary by the scale of the operation. The metal formed sinks in the bath because its specific gravity, melted, is 2.54, while that of the bath varies between 2 and 2.35, at most. The temperature of the operation is 900° C. (1,650° F.). One bath will continue in uninterrupted operation several months, the carbon anodes being renewed as they burn away, which they do at the rate of 1 pound of anode per pound of metal produced.

trodes by an electric-furnace process described in Hall's United States patent 705,076 of July 22, 1902.

The commercial production of aluminium in America is, therefore, wholly by the application of Hall's process of electrolytic reduction, supplemented by Hall's lime or electric-furnace process of purifying alumina and the same inventor's process of baking carbon electrodes. It was not the purpose of this article, however, to enter into detail on the commercial side of the production of aluminium, and we will conclude by discussing the reactions taking place in the process, *i. e.*, by regarding the scientific aspect of the process.

First, as to the facts. Cryolite, the sodium-aluminium double-fluoride, melts at 800° C. When melted, it is transparent and one can see through several inches of it to the bottom of the vessel containing it. If powdered alumina is stirred into it, it largely dissolves at once, without ebullition or evolution of heat or any signs of chemical action. If a large amount is added at once, some will be seen at the bottom

of the melt gradually dissolving and disappearing. About 20 per cent. of the weight of the bath can be thus taken up, and the bath remains homogeneous; if over 25 per cent. is added some remains undissolved at the bottom. Neither the bath material alone or the solution containing alumina wets, *i. e.*, adheres to, carbon. Carbon rods or even powdered carbon stirred into the bath, rise to the surface and emerge without the bath material sticking to them. On passing a direct electrolytic current through this bath aluminium appears at the cathode, and oxygen at the anode. If the anode is of carbon, carbonic oxide is there evolved; if it is of bright copper, a skin of cuprous oxide first forms on it, and afterwards oxygen is evolved. If the alumina in the bath is allowed to become exhausted, fluorine commences to evolve at the anode; if a very high current density is used sodium vapor shows itself at the cathode. The working temperature of the bath is 900 to 950 C., and its specific resistance is about 3 ohms per centimeter cube.

Mr. Adolphe Minet has made a number of measurements of the resistance and electromotive force required for decomposition in baths containing 60 per cent. of sodium chloride, and it is, therefore, not at all certain that his conclusions apply to the present manner of manufacturing aluminium. He concludes that in a bath containing sodium fluoride, sodium chloride and aluminium fluoride, mixed together, the aluminium fluoride must be decomposed, because it is the weakest of the three salts, and the salt thus removed may be returned to the bath by piling alumina around the anode where it may be converted into fluoride by the evolved fluorine. He claims that when alumina is added to such a bath it does not dissolve, but remains mechanically suspended, and so regenerates aluminium fluoride by being decomposed by the fluorine evolved at the anode. As stated above, the presence of an excess of sodium chloride vitiate all Minet's conclusions, as applicable to Héroult's and Hall's processes, and, furthermore, all the phenomena of the electrolysis of Hall's and Héroult's baths point to a different explanation.

Héroult himself advanced the even less plausible theory that sodium was primarily evolved at the cathode and fluorine at the anode, that the sodium then acted upon the aluminium in the electrolyte as aluminium fluoride and reduced out its metal, while the fluorine at the anode acted upon the alumina suspended (not dissolved) in the melt, and set free its oxygen, forming aluminium fluoride. This theory is such a maze of contradictions as to be indefensible. Primarily, the disappearance of alumina stirred into the bath is proof of its becoming incorporated into the electrolyte, and any electric current passing through would separate aluminium at the cathode in preference to the more positive sodium. The theory of Héroult, unsustained by any experimental proofs to establish his position, is certainly untenable.

In the writer's opinion, and from his repeated observation of the process and experimenting with it in various ways, the conclusion of Mr. Hall that he really has a solution of alumina in a fluid bath analogous to a salt dissolved in water, is the best explanation of the facts. The alumina dissolves apparently like sugar disappearing in water, without ebullition, evolution of gas or heat, or any appearance of chemical action. If the result is an oxyfluoride bath, as some think, it may be well to note that an oxyfluoride is merely a combination of $Al^2O^3$ and $AlF^6$, and the union, if it exists at all, is chemically a very weak one. When a salt goes into solution in water, the hydrate theory of solution assumes the existence of possible combinations of salt and water in the solution, but of such a weak character of combination as to practically be negligible as compounds. With these facts in mind, it appears that the statement of Mr. Hall that his alumina *goes into solution* in the bath is a very exact statement of the phenomenon.

As concerns the decomposition of the bath, everyone who has worked with the process knows that aluminium appears at the cathode and oxygen at the anode. The most evident inference is that the alumina in solution is decomposed, and its constituents appear at the electrodes. Anyone who would maintain that the primary electrolysis proceeds otherwise and that one or both of these products are secondarily produced, must certainly shoulder the burden of proof to support his view. But, when we come to analyze the reaction, and discuss the probability of secondary reactions occurring, we find the probabilities all in favor of the decomposition into aluminium and oxygen being primary.

There are present in the bath, or, at least, go into its composition, sodium fluoride, aluminium fluoride and alumina. The heats of formation and voltages theoretically necessary for decomposition of these salts are as follows:

Sodium fluoride (Na, F) = 109,700 calories, requiring 4.7 volts.

Aluminium fluoride (Al, $F^6$) = 296,000 calories, requiring 4.0 volts.

Aluminium oxide ($Al^2$, O) = 392,600 calories, requiring 2.8 volts.

With these substances going into the composition of the bath there is not the slightest doubt but that aluminium and oxygen should be primarily separated out at the electrodes on passing the current. The facts are that these products do appear, and the burden of proof is certainly on anyone who would maintain that the reaction is in any way different from the above. If a carbon anode is used, carbonic oxide appears, and only traces of carbon fluoride; if copper is used, it coats itself with oxide, not with fluoride, and afterwards pure oxygen is evolved. The writer cannot understand how anyone can doubt the primary evolution of oxygen and aluminium from the bath, if they are acquainted with the details of the process and its mode of working.

Haber and Geipert published in the *Zeitschrift für Elektrochemie* for 2d and 7th January, 1902, the results of some laboratory tests of this process on a rather large scale, using a current up to 400 amperes. They obtained about 50 per cent. of the theoretical output, and remark that the electrolysis of this solution of alumina proceeds as quietly and regularly as an analytical determination in aqueous solution. They determined to their complete satisfaction that only traces of carbon fluorides were evolved during the electrolysis, and that the bath will not take up uniformly above 20 per cent. of its weight of alumina. With their small apparatus they found a current density of .3 amperes per square centimeter of floor surface kept the bath fluid, while in large manufacture one-third that much suffices. The difference is due entirely to working with 300 amperes or several thousand. They used a working voltage of 8.5, whereas on a large scale only two-thirds that voltage is necessary, using the lower current density.

Prof J. W. Langley has recently given, in the "Transaction of the American Electrochemical Society," Vol. II, page 200, the results of measurements of the counter-electromotive force in electrolyzing alumina dissolved in melted cryolite at 1,010° C., using 1,000 amperes of current. The measurements were only approximate, but showed a counter-force rising to 1.22 volts during continuous electrolysis by 5 to 10 volts applied. This is not the disruptive work of the current, but, as Prof. Langley happily phrases it, is "the instantaneous value of the counter electromotive force existing *during the passage of the current*." It is very probably the measure of the tendency of metallic aluminium to decompose the carbonic oxide gas at the anode and form the lowest oxide of aluminium. But, the current is decomposing the highest oxide of aluminium, and, therefore, the voltage absorbed in decomposition is higher than the counter-electromotive force.

The writer has satisfied himself, from measurements of the current in amperes passing through the bath, using different potentials, that the chemical work being done by the current is represented by nearly 2.2 volts, which corresponds to the decomposition of alumina (2.8 volts) minus the energy furnished by the oxidation of the carbon (0.6 volts). Prof. Lang

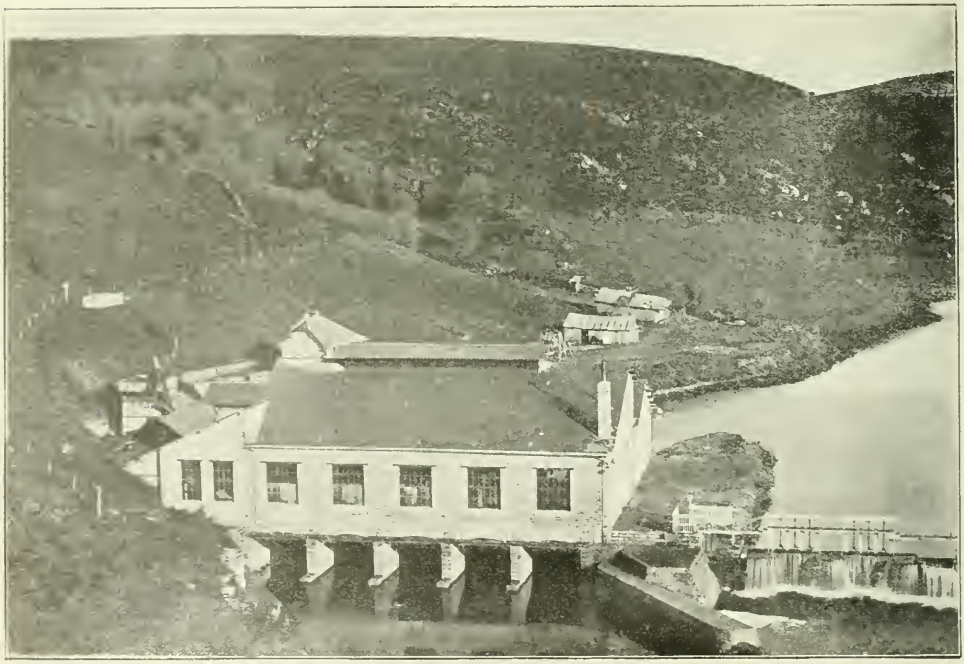
determination of the counter-electromotive force being 1.42 volts is not inconsistent with this; it simply means that if the current is suddenly thrown off, the ions at the electrodes do not tend again to form alumina and carbon, but sub-oxide and carbon, with a total energy evolution measured by 1.22 volts.

It is a pity that a process of such beautiful simplicity, theoretical interest and commercial importance has not been more closely studied, and more definitely described. Commercial reasons have doubtless actuated the workers of the process in keeping all its details as secret as possible, but it is to be hoped that the awakening of electrochemical industries which has taken place in the last year or two will soon touch this field, and help us to fill some of the gaps in the scientific understanding of this process. The writer is convinced that a clearer understanding of the modus operandi of this process would undoubtedly lead to fruitful results in the application of similar principles to the extraction of some of the other electropositive metals.

white snow mountains with their waterfalls, available for generating power.

Among the papers read at the congress was one of special interest, as it dealt with an entirely new electrochemical industry. Its author was Mr. Charles Bertolus, electrometallurgist at Saint-Etienne (Loire); and the subject of the paper was the manufacture of different kinds of steel in the electric furnace in the Kerrousse plant of Keller, Leleux & Co. For a copy of the paper, as well as for the cuts and for some valuable additional notes, we are indebted to Mr. P. McN. Bennie, European manager of the International Acheson Graphite Co.

The plant at Kerrousse, near Hennebont (Morbihan), was erected by Keller, Leleux & Co. for the purpose of manufacturing calcium carbide; but when it was nearly completed, the French courts handed down a decision awarding to Mr. Bullier all patent rights to make calcium carbide in France, so that the plant at Kerrousse was prevented from starting the manufacture of carbide. As the apparatus for electrometal-



KERROUSSE PLANT.

## A FRENCH PLANT FOR MAKING STEEL IN THE ELECTRIC FURNACE.

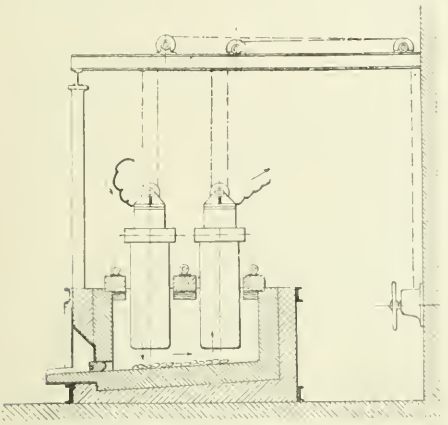
In Europe, France may be considered to be the country par excellence of water-power development. Especially in the French Alps a great number of hydro-electric stations were erected in recent years, and a remarkable rise of electrochemical industries took place in connection with this development. As the possession and development of a water-power in France is governed by certain laws, this industrial development was somewhat influenced by legal restrictions. To thoroughly discuss the legal and the industrial aspect of the case, all those interested in water-power development in France, united last fall at Grenoble in the "Congrès de la Houille Blanche," *i. e.*, in literal translation, "White Coal Congress," attributing the poetical name "white coal" to the

lurgical operation had been installed, it was decided to utilize the plant partly for the manufacture of ferro-alloys and partly for making steel in the electric furnace. The latter process is described in the paper of Mr. Bertolus.

The plant at Kerrousse utilizes a waterfall of the river Blavet of about 550 horse-power. There are four vertical turbines each of 135 horse-power, coupled at will to a horizontal shaft driving two alternators of 200 kilowatts each, and two exciters. The alternators are designed to give current at three different voltages, according to the external circuit to which they are connected, and according to the special electrometallurgical process for which the current is used.

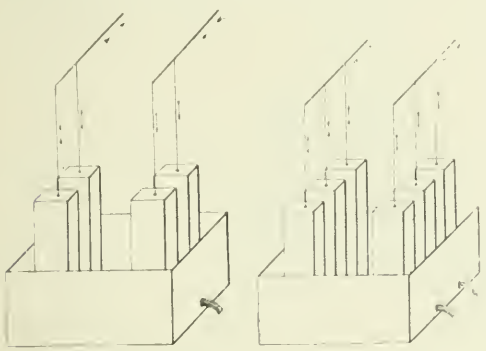
The furnace room is divided into two parts: one-half contains four electric furnaces for making ferro-alloys, the other half special electric furnaces for treating iron ores and making steel.

Mr. Keller, a member of the firm which owns the plant, obtained his first satisfactory results in the treatment of iron with his "two-electrode furnace. This furnace contains two vertical electrodes, placed side by side; the furnace has walls of brick and a refactory bottom. At each electrode a distinct



TWO-ELECTRODE FURNACE.

zone of high temperature is produced, and these two high temperature zones are in series with the fused or partly fused materials between them. Either high temperature zone may be separately regulated, by a simple movement of the electrodes. This two-electrode furnace has, however, two dis-



FOUR-ELECTRODE FURNACE. SIX-ELECTRODE FURNACE.

advantages: the capacity of the furnace is limited and the continuity of operation is interrupted whenever an electrode is to be renewed. These disadvantages are successfully overcome by using four or six or more electrodes, one-half of the electrodes being connected to the positive pole of the circuit, the other to the negative pole. It is evident that with this arrangement there is practically no limit of the dimensions of the furnace, and that a single electrode can be replaced without interrupting the whole operation.

In his first experiments Mr. Keller used the same apparatus for the reduction of the iron ore and for the subsequent conversion into steel. There was the disadvantage that both steps require different treatment. To enable economical reduction of the iron ores, the furnace must be able to accommodate a considerable quantity of the materials to be treated; on the other hand, for refining purposes a rather shallow furnace is required with the material held in a condition of perfect fluidity and easily accessible. These reasons lead to the adoption of two electric furnaces "en cascade" (in tandem), the upper furnace being intended for the reduction of the iron ores, and the lower furnace for the subsequent refining and purification process. As each furnace serves a special purpose, it is designed to meet the special demands of this purpose. This is the arrangement of the 375 horse-power furnace which we will describe later. It may be mentioned that Mr. Bertolus in his French paper always speaks of the "haut-fourneau électrique." Mr. P. McN. Bennie remarks that a new name seems necessary for this type in English; it might be translated as blast furnace, because the general appearance is that of the ordinary blast furnace, although in the electric furnace there is no "blast."

The upper furnace has four electrodes; the bottom is inclined towards the tapping hole. Above the fusion chamber of the furnace there is a column made of brick, and into this shaft the ores, the carbon for reduction, and the fluxes are fed. Below the tapping hole of the upper furnace, the lower furnace is placed which receives the cast iron; it can be closed by removable covers of refactory material and is provided with two electrodes the position of which is adjusted by hand.

When the operation begins, the materials to be treated are fed into the shaft at the top of the furnace. In order to observe the condition of the separate high temperature zones at the end of each of the four electrodes, four ammeters are provided, one in the circuit of each electrode, and two voltmeters; the regulation is then accomplished by a movement of the electrodes. The fusion and reduction of the ore starts at the bottom of the furnaces. The gases developed rise to the upper part of the furnace and are then burned in a suitable chamber, in order to utilize the heat for drying fresh material to be fed into the furnace.

After several hours, the molten metal is drawn off into the lower furnace which has been previously heated and already contains fused materials. When the metal has been drawn off from the upper furnace down to the slag, the tapping hole is closed, and new material is fed at the top into the upper furnace. After a certain time the slag of the upper furnace is discharged through an opening provided for this purpose in the side of the furnace. The slag and the metal are examined at regular intervals, and it is possible to obtain a metal of absolutely uniform composition.

When the lower furnace contains a sufficient quantity of liquid metal, the process of refining is started; the current is so adjusted as to accomplish perfect liquidation and rapid reaction of the metal with the refining and purifying agents.

Mr. Bertolus remarks that the rough metal may be decarburized either by adding oxide to the bath, the oxide added being the iron ore itself, or by the addition of scrap iron. The purification is brought about by a suitable addition of lime. Samples are taken at regular intervals, to determine the stopping point of the process of decarburizing and purification. The further treatment seems to be the same as in the ordinary metallurgical process.

Mr. Keller, who is personally in charge of this process, remarks that on account of the relatively small amount of power at this point, it was not thought to be advisable to install certain additional improved apparatus devised by him for the manufacture on a large scale. He claims that his new apparatus would enable him to cast and refine quantities of steel of 15 to 20 tons at the same time, or even more if necessary. Mr. Bertolus states that he was also present when the process of making steel from scrap iron was worked; this process requires somewhat different electrical conditions.

The principal point is, of course, the cost of the process, and for this reason we give herewith a literal translation in full of the portion of Mr. Bertolus' paper, dealing with the cost of the process. The figures given are, of course, based upon the conditions in France; we have changed the figures from French into American money, 5 francs being assumed to be one dollar.

"We have verified that the manufacture of one ton of steel

require 2,800 effective kilowatt hours, say, about 3,800 electric horse-power hours. To determine the cost in the case of the direct treatment of the ore, we assume as a basis the following prices which are taken from ordinary practice:

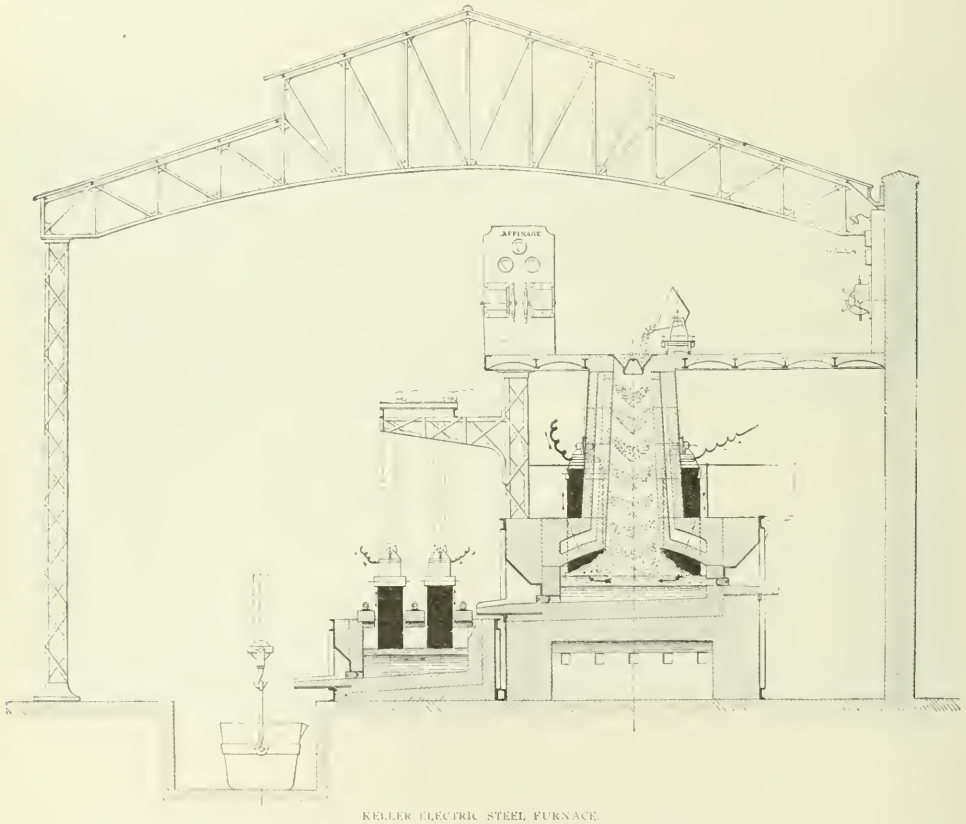
| | |
|---|---|
| One ton of iron ore, containing 55 per cent. of iron, delivered at the plant | $2. |
| One ton of coke for reduction, delivered | 8. |
| One ton of flux, delivered | 3. |
| Price of labor per day | 0.60 |
| 100 kilograms of electrodes, delivered | 6. |
| Electrical energy, per kilowatt year of 8,400 hours | 10. |

This last price includes depreciation of the buildings and of the machinery. In the case of a plant of average size, the cost of manufacture of a ton of steel includes: 1. Raw materials (ore, coke, electrodes, fluxes, and special materials). 2. Electrical energy. 3. Labor. 4. Maintenance (maintenance in general, ingot moulds, refactory materials, tools). 5. General current expenses. 6. Deterioration; and the total cost* may be assumed to be about $18.

One may therefore conclude that the ton of steel made by the electric treatment direct of the ore and cast into ingots, not including the license of manufacture, can be made at a cost of $18 to $20, in round figures. For exceptionally low prices of raw materials and electrical energy the cost of manufacture could be, of course, diminished."

In the manufacture of steel from scrap iron, the output of a furnace is greater for the same power, than in the manufacture of steel direct from the ore; hence the electrical energy enters into the cost of one ton of steel as a less important item in the first case than in the second. On the other hand, in the cost of manufacture of one ton of steel, the scrap iron represents generally a larger item than the ore and the coke together. Whether the one method is superior to the other, depends therefore only on the geographical situation of the plant.

Concerning the quality of the steel produced in the Keller furnace, Mr. Bertolus reproduces extracts from a report on tests made with an ingot of this steel by the metallurgists of the Basin de la Loire. He concludes that the quality of the ordinary steel made in the electric furnace is fully satisfactory to metallurgists; the electric steel can enter into competition with the Martin (open hearth) and Bessemer steel. As in



KELLER ELECTRIC STEEL FURNACE.

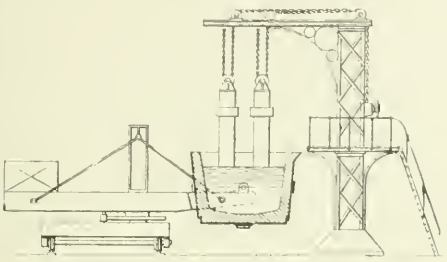
the electric furnace the heat produced is not due to an oxidizing agent, the steel which is made electrically is less liable to contain oxides of iron in solution and it can easily reach the quality of crucible steels. Moreover in comparison with the crucible process, the manufacture of steel in the electric furnace has the great advantage that it can be undertaken on a much larger scale and "it is absolutely certain that very soon the small crucibles containing 30 kilograms of steel which are at present used in the large metallurgical plants, will be replaced by large electrically-operated crucibles containing several thousands of kilograms of metal."

This is essentially the contents of Mr. C. Bertolus' interesting paper. We are indebted to Mr. P. McN. Bennie for the following additional information on improved apparatus

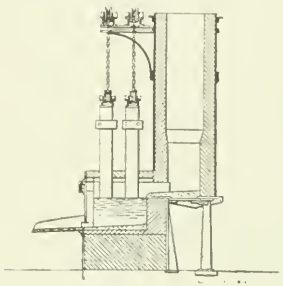
* Presumably per metric ton, *i. e.*, 1000 kg. or about 22.0 pounds.

recently designed by Mr. Keller and shown in two adjoining diagrams. The one shows an arrangement in which the refining furnace is mounted upon a truck running on rails, so that it may be moved along a series of electric furnaces; the one refining furnace thus serves the whole series and is therefore almost in constant use, the economy of the process being thereby increased. The other diagram shows an arrangement in which the refining furnace is operated in conjunction with the ordinary foundry cupola.

Mr. P. McN. Bennie points out that the problem should



LADLE FURNACE.



CASCADE FURNACE.

be of great interest to American metallurgists in view of the great water-power developments in the neighborhood of the Lake Superior ore deposits, and of the titaniferous iron ores in New York State and Canada. On the other hand, he calls attention to the fact that the application of electric-furnace methods is not restricted to regions with water power. The blast-furnace gases may be utilized for driving gas engines coupled with electric generators, so that the electric-furnace process might be worked in conjunction with blast furnaces.

## SOME LABORATORY OBSERVATIONS ON ALUMINIUM.

By Prof. C. F. Burgess and Carl Hambuechen.

WHILE Nature has rewarded modern ingenuity and enterprise in giving to mankind one of her most important treasures, she has withheld much of the knowledge relative to this important metal which is necessary in order that it may be utilized to greatest advantage.

Aluminium having become a material of every-day use, our familiarity with it is conducive to the idea of intimate acquaintance. That we are not thoroughly acquainted with it, however, is shown by the very contradictory and misleading statements made in all sincerity, even by leading authorities, relative to the properties of this metal. But it cannot appear strange that our knowledge of this metal is deficient when a thorough study reveals the fact that we really know little about the oldest and most important structural metal—iron.

Each addition to our knowledge of the properties of aluminium points the way for new applications of the metal, and the extent of its use in the future can be judged best by estimating the increase of knowledge regarding its properties. The adaptability of aluminium for a new and previously untried use can be estimated best if not alone by actual trial. Experience is, particularly in this case, the best teacher, for what reliance could be placed upon advice such as that of which the following statements quoted from authorities of note give a common illustration? "Aluminium is unaffected by either sulphuric or nitric acids," and "Sulphuric and nitric acids act immediately upon aluminium."

There are certain properties of this metal which, while known by some for a long time, have not become matters of general information. It is the purpose to point out in this paper a few such features, and to give data and results of observations made in the laboratory of applied electrochemistry of the University of Wisconsin during the past two years. Some of these observations are both contradictory and confirmatory of previously published statements, and certain other observations, it is believed, are pointed out here for the first time.

The properties which are especially peculiar to aluminium are, in some cases, obstacles which have to be encountered and overcome in adapting the metal to certain uses, and in other cases these same properties are the ones which enable the metal to be employed for purposes that no other metal can fulfill.

Aluminium has not been used for a sufficient length of time to enable certain properties, such as corrodibility under various atmospheric conditions, to be determined. It is called by some a very corrodible metal, and by others a very durable substance, depending perhaps upon the point of view, whether theoretical or practical. Theory might indicate that aluminium occupying an electropositive position in the electrochemical series of elements may be expected to become oxidized or acted upon by an oxidizing agency with much greater readiness than all the other common metals, and this is borne out in the Goldschmidt reducing process, where aluminium, in a finely divided form, is used as a strong reducing agent. Further, if an aluminium plate be thoroughly amalgamated and exposed to the air, it will oxidize so readily as to form in a few minutes a thick, white, voluminous layer of aluminium oxide, and the plate will become so hot as to be uncomfortable to the hand. There are no other common metals which will "burn up" so readily when placed in contact with the air.

We have, on the other hand, however, the fact that this metal may be placed in contact with either dilute or concentrated nitric acid and the corrosive action will be extremely slow, and with sulphuric acid it will also be so slow as to escape detection unless observed for a considerable length of time. Inasmuch as aluminium will resist the oxidizing action of these strongest oxidizing agents, in a degree which none of the other metals, with the exception of gold and platinum, can equal, there has been some ground for the statements that aluminium behaves as a noble metal, and can be used for the cathode of a primary battery.

Many of such contradictory conclusions regarding aluminium may be based upon such factors as the use of impure aluminium in one case and aluminium of a high degree of purity in another, differences of temperature and various other considerations, including perhaps the most important of all, the well known supposition that aluminium is covered with a thin, invisible protective film, which, under certain conditions, effectually prevents contact of the metal itself with the air, solution or other surrounding influences wherever such surrounding influences are not such as to destroy this coating. This film is supposed to have considerable strength and continuity, and if it is broken or removed by mechanical means the aluminium immediately forms a new one. If, therefore, this metal could be used as a structural material for bridges,

the maintenance of such structures would not involve an annual expenditure for painting, since they would "paint themselves."

There has been some difference of opinion as to whether such protective coating really exists, and, if so, whether it is that which influences or determines the apparent properties of the metal. It is true that the coating must be very thin; it can barely, if at all, be detected by the microscope, and it is impossible to collect enough of it for determination of composition by chemical analysis. It is variously held to be a continuous coating of aluminium oxide, or a basic compound, or a hydroxide, etc. The chemical composition has never been determined with any degree of assurance. Suffice it to say that experimental evidence seems to prove that such film exists, and some of the facts bearing on this point will be referred to in the following.

Among the problems which have received much attention, and the satisfactory solution of which has an important bearing upon the extent of the utilization of the metal, are the soldering, the electrodeposition of various metals upon aluminium and the electrodeposition of aluminium upon other conducting surfaces.

Aluminium alloys readily and through a wide range of proportions with other metals, a fact which might naturally point to the conclusion that the soldering of aluminium should be an easy matter, as should also the deposition of other metals upon its surface. Practice has shown, however, that success can be attained only by most careful operation. The principal difficulty in soldering aluminium seems to be due to the failure of the alloy used as a solder to adhere to the aluminium, a condition attributable to the protective film, which must be eliminated before the metals can unite. A great many suggestions have been made and processes patented for doing this work, although only a few have proved practical. The various methods may be classified in the divisions: those using a flux; those employing a special solder which works its way over the surface without a flux, and those depending upon the mechanical abrasion or cleaning of the surface while the solder is being applied. Combinations of the above may also be used.

The higher the temperature to which aluminium is heated, the greater is the ease with which the solder will unite, and by heating to the softening point and scratching the surface almost any solder which will melt at that temperature will flow over the aluminium surface. Possibility of damage to the aluminium article, together with the inconvenience of working at this high temperature, makes such process impracticable for most purposes, and it is really a welding rather than a soldering process.

It has been found that certain solders, properly proportioned and compounded, can be applied to aluminium quite readily without the use of a flux, and at a temperature such that the ordinary soldering copper can be used. The "tinning" of the surface is facilitated by mechanical abrasion while the solder is being applied. Of the various metals entering into the composition of such solders, the most important are zinc, tin, aluminium, lead, nickel, copper and bismuth. Just what functions the different ingredients fulfill is perhaps unknown. It may be that certain metals give to the solder the ability to work its way or flow by capillarity or otherwise under the surface film on the aluminium, and thus alloy with the metal. Zinc seems to possess this property to the most marked degree.

A successful solder of this sort, which is now on the market and in quite extensive use, has a composition something as follows: Zinc, 21 per cent.; tin, 76 per cent., and aluminium, 3 per cent. This may be applied directly to a cleaned aluminium surface without the use of a flux, and at a temperature but little above that which is necessary for soldering copper or iron.

There are certain advantages in the apparent complication which the use of a flux involves. A suitable solvent for the oxide film increases the rapidity of the soldering process, increases the certainty of adhesion and enables cheaper soldering mixtures to be employed. The requirement for such a flux is that it should dissolve the coating and leave a clean surface for the solder to unite with upon application of heat. While there are various aqueous solutions, such as hydrochloric acid, hydrofluoric acid and ammonium fluoride, which are solvents for the aluminium coating, none of these substances will leave a clean surface after the application of heat. The results of a large number of tests with different materials seem to point to the fact that water cannot be a component of a suitable flux. Following this idea, a flux was made up by means of which any ordinary solder, such as 50 per cent. tin and 50 per cent. lead, may be made to readily unite with an aluminium surface which had not been previously cleaned. Such material contained potassium fluoride as the principal ingredient, potassium fluoride and resin being dissolved in acetone and a little zinc chloride added to harden the mixture. By exposure to the air, a partial solidification takes place, the resultant pasty substance being in a form suitable for a flux.

Another material which, for certain solders, forms an admirable flux is stearic acid. By applying this to a freshly-scraped aluminium surface, and then applying a tin-lead-zinc alloy, the matter of soldering aluminium presents scarcely greater difficulties than does the soldering of other metals.

This almost ever-present coating upon aluminium is the source of difficulty in the deposition of a permanent coating of other metals upon aluminium surfaces. Although aluminium itself presents a surface to atmospheric conditions which ordinarily needs no further protection by other metals and maintains a pleasing appearance, still there are many cases where it is desirable, for ornamental and protective purposes, to apply to it a durable coating of other metal. Aluminium continually coming in contact with the hands, and subjected thereby to the action of the perspiration, undergoes corrosion somewhat rapidly. A certain instance has come to the writers' attention where an aluminium handle on a certain form of tool corroded so rapidly as to become useless in a few weeks. The advantage of a protective coating of some other metal is, in this instance, evident, and many other similar cases might be cited. There is also a growing demand for gold and silver plating on aluminium objects, such as toilet articles, tableware, ornaments, etc., and a cheap and successful method of performing this operation will be of advantage to the aluminium industry.

The obstacles in this matter are, first and last, the difficulty in electrodepositing a metal which will stick. While it is a very simple matter to deposit a layer of metal upon aluminium from almost any plating solution, in the great majority of operations the resulting coating can be readily removed; sometimes in remarkably thin and continuous layers, and it is only by observing certain precautions that the resultant coating will stand the buffing or polishing operations. The writers have employed aluminium plates in the production of thin sheets of zinc, nickel and other metals, such metals, after being deposited to a desired thickness, having been separated from the aluminium by means of air pressure. Even though the coating may apparently adhere and stand the buffing operation without blistering, the success of the coating is not insured; subsequent exposure to moisture may cause the coating to become loose, or, even if no external moisture be present, the solution which may have been inclosed in the pores of the metal may spread out and cause separation of the coating.

The prime requisite in successful deposition on aluminium is the complete removal of the protective film, so that the electrodeposited metal may be applied over the complete surface of and in intimate contact with the aluminium. If this condition is fulfilled and the coating is non-porous, it will be durable.

Various formulas for carrying out this operation have been published and patented, and, while the majority of them are unsuccessful and misleading, there are certain methods of procedure through which successful results may be attained. The limits of this paper, however, do not allow a discussion of the

various processes which may be employed. As a result of laboratory investigation, it has been found that the deposition of metals upon aluminium can be carried out with the same ease, and with practically the same durability of results, at least as far as tests covering one year's time would indicate, as upon iron and other metals.

The converse of this operation, however, the electrodeposition of aluminium upon other metals, is an entirely different matter. The desirability of performing this operation has long been recognized, and has led to much experimental investigation on the deposition of aluminium from aqueous solutions, the principal object being to make the corrosion-resisting properties of aluminium available in the protection metal surfaces from corrosion, thus affording a more efficient protection than tinning or galvanizing, as now applied. Such process has not as yet shown any signs of development, although statements have been made from time to time since the discovery of aluminium that success had been attained in the deposition of aluminium from aqueous solutions, some of these statements having been contributed by men of note in the scientific world. Whether we shall conclude that such statements have been purposely misleading or made as a result of erroneous conclusion, and explain the fact that no electrolytic aluminium plating has been exhibited for public inspection because secrecy has to be maintained in regard to it, the fact is that this process has shown no outward signs of commercial success. A method of depositing aluminium from aqueous solutions would find application not only for ornamental and protective purposes, but, if such a process had been discovered, it would be heralded as a means for obtaining aluminium from its compounds.

While there do not seem to be any laws of nature which prohibit the deposition of aluminium from aqueous solutions, and while it is not beyond the range of possibility that a suitable means for doing it may be discovered, the probability is that a solution other than an aqueous one must be used. Evidence seems to point to a fact that where water is present the deposition of aluminium is prevented.

The adaptability of aluminium for electrode purposes has received some attention at the hands of electrochemists. There are certain limitations which make it unsuitable for most electrolytic operations. When used as the cathode, the tendency of the reducing action and of the gases liberated is to remove the protective film, and thus cause continual exposure of the plate to the solution and its consequent corrosion. In aluminium we have one of the few instances where the cathode is corroded, and in some cases the results are quantitative and in close agreement with the requirements of Faraday's laws.

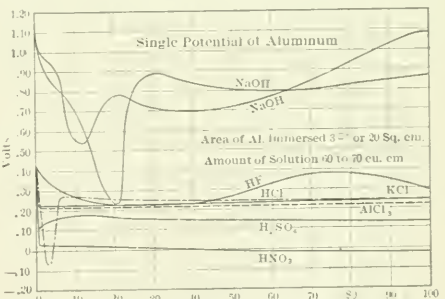
The fact that aluminium separates readily from a metal which has been electrolytically deposited upon it may be utilized to advantage in certain cases. It has been proposed to use this metal for cathodes in the electrolytic recovery of gold from cyanide solutions, the gold being easily collected as soon as a sufficient thickness has been attained, thus avoiding a smelting operation, as where lead cathodes are employed.

Aluminium as an anode frequently presents striking characteristics, due to the fact that the oxidizing action at the anode in many solutions tends to increase the durability and insulating power of the protective coating, with the result that the current may be entirely interrupted, even if a high pressure be applied. This coating has the property also of freely allowing current to flow from the electrolyte to the electrode although not in the reverse direction, and the effectiveness with which this operates enables it to be used as an efficient check valve for the electric current, making it possible, among other uses, to obtain a unidirectional current from alternating current circuits.

If two aluminium plates be placed in a sodium potassium tartrate solution, and an alternating pressure of about 50 volts be applied, a view of the plates in a dark room will show a distinct phosphorescence; an increase of pressure causes an exceedingly beautiful sparkling, which, on close inspection, bears a resemblance to the appearance of the heavens on a clear night, with even an imitation of the milky way; and a further increase of pressure causes a more marked sparkling effect of great brilliancy, and the possibility of adapting this phenomenon to advertising and display purposes at once suggests itself. This appears especially practical when an examination of the electrical instruments show that a very small amount of energy is necessary in producing a considerable degree of illumination, and the impression which is obtained from a bright illumination under water is sufficiently startling to be attractive.

Another way in which aluminium may play an important part in an electrochemical manner is in its use as the metal to be consumed in a primary cell for the production of electrical energy.

From the fact that, for equal weights, aluminium possesses about four times the energy as does zinc, some considerable attention has been given the matter of substituting the former metal for the zinc commonly used in primary cells or electrochemical generators of electrical energy, and various patents have been granted on means for accomplishing this. Aluminum, being a more electropositive element than zinc, might be expected to give, in combination with suitable cathode and electrolyte, a higher electromotive force than does zinc under similar circumstances. The present price of aluminium places that metal on something of a par with zinc, as far as cost of



POTENTIAL CURVES OF AN ALUMINIUM ELECTRODE.

generation of electrical energy is concerned, and the higher electromotive force and greater lightness of aluminium make it a desirable material for battery purposes when considered from the theoretical standpoint. As a matter of fact, however, aluminium does not behave well as the electropositive metal of a battery and attempts to use it in practice have almost universally failed. Its failure to give the results which might be expected can again be attributed to the partially insulating compound which forms on the aluminium surface.

The conditions under which aluminium sets up and maintains the highest values of electromotive force, together with various other factors concerning this metal, is the subject of investigation which is being carried on in our laboratory by Mr. W. R. Mott. The accompanying tables and curves derived therefrom give some of the values determined by him. These show some interesting facts concerning the behavior of aluminium in various electrolytes.

The values of single potentials here given are based upon the normal "calomel" electrode the potential of which is assumed as + 0.56 volt. By measuring between this electrode and the aluminium in contact with the respective electrolyte and deducting the value of the normal electrode, the value of single potential of the aluminium is determined.

The measurements were made as follows: Strips of aluminium, about 3 inches long and ½ inch wide, were cut from an aluminium sheet just as obtained from the factory. Without any preliminary cleaning or special treatment, they were immersed in their respective solutions, and a reading of potential made immediately after immersion. The strips were then

left in the solutions for about one hundred hours, and readings of potentials made at intervals during that time.

TABLE OF SINGLE POTENTIALS OF ALUMINIUM IN VARIOUS ELECTROLYTES.

| Time in hours | | 0 | .5 | 1.5 | 5.0 | 6.2 | 21.6 | 27.9 | 77.9 | 99.9 |

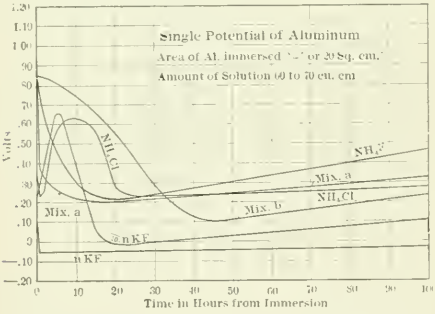
| 14. | Mix. *a* | .925 | .370 | .310 | .280 | .250 | .220 | (*) | .274 | .262 |
| 15. | Mix. *b* | .760 | .550 | .820 | .790 | .778 | .520 | .286 | .187 | .235 |

(*) On allowing current to flow, potential rose from .220 to .403 volt.

Solutions 1, 4, 5, 6, 7, 9, 10, 11 and 12 were normal solutions; 2 was dilute solution of aluminium chloride, commercial; 3, dilute solution of pure aluminium chloride; 8 was 0.1 normal solution of sodium hydroxide; 13, a 0.1 normal solution of potassium fluoride; 14, a mixture of equal parts of normal ammonium chloride and normal ammonium fluoride; 15 was a mixture of normal ammonium chloride and 0.1 normal potassium fluoride.



POTENTIAL CURVES OF AN ALUMINIUM ELECTRODE.

From the first column of values, it will be noted that the potential of aluminium at the moment of immersion in various electrolytes has widely different values, depending upon the solution employed. The lowest value here given is 0.01 volt in potassium fluoride, and the highest 1.147 volts in sodium hydroxide.

The data here given would point to the conclusion that, of the various materials tested, ammonium fluoride would be the best material to use in connection with aluminium for battery purposes, the use of this being analogous to the use of ammonium chloride in connection with zinc in the ordinary type of open-circuit cell. Tests which were made showed that an aluminium-consuming cell of this type would set up a pressure of almost 2 volts. The factors governing commercial operation, such as constancy of pressure on open and closed circuit, the consumption of aluminium and electrolyte, polarization, etc., have not been completely investigated.

It will be noted, from measurements taken at intervals covering a period of one hundred hours, that the general tendency is for the single potential to decrease, though there are instances when the pressure increases to some degree. The variations are shown in the curves, some of which exhibit marked irregularities, which may indicate certain properties of the metal, or they may have been accidental, the results of errors of observation or other factors. An investigation of such irregularities is the subject of further investigation.

Aluminium shows greater variations in its contact potentials with different solutions than perhaps any other metal. Chromium has been shown to exhibit three widely different values of single potential, depending upon different stages of oxidation which it may undergo, it being capable of combining in three different valencies. A similar assumption in the case of the variations in the single potentials of aluminium can hardly hold, and the explanation must be sought elsewhere. One such is that in certain cases, those in which we obtain the highest values, it is the potential of the metal itself which is being determined. In other cases it may be that the aluminium, wherever its protective coating is fractured or perforated so as to allow its coming in contact with the solution, coats itself with a layer of hydrogen, and it is really the single potential of hydrogen which we are measuring. Or, further, the aluminium coating may itself set up a single potential, being a conductor of sufficient conductivity to allow the measurement being taken, and there seems to be some evidence pointing to different kinds of coatings in different solutions.

The influence of the protective coating which normally exists on aluminium, after exposure to the air, is shown in the curve for ammonium chloride. The potential upon immersion is low, then rises for several hours, indicating a very slow dissolving action of the solution upon the coating, and then the potential gradually falls. The maximum point in the curve comes very much quicker, as shown in curve for mixture *b*, No. 15, where a small amount of potassium fluoride, a partial solvent for the coating, was present. With mixture *a*, No. 14, the solvent action of the ammonium fluoride was so great as to cause the aluminium to assume its maximum value of potential immediately upon dipping in the solution.

The data here given shows a number of notable peculiarities, one being the fact that aluminium in contact with the normal potassium fluoride solution gave a much lower value, at least for the first half of the time, than did the one-tenth normal solution of the same salt. A change of concentration, with a solution of ammonium nitrate from 0.018 normal to 4.66 normal, produced a difference of only 0.1 volt, and the change of value did not seem to be a function of the concentration.

It is possible that some of these peculiarities may be explainable on errors of observation, or they may be due to different physical condition of the aluminium samples, although care was taken to cut all the pieces tested as nearly of a size as possible from an aluminium sheet and subjecting them all to similar treatment. That the physical condition of the aluminium may exert a large influence was shown by measuring the potential of an aluminium strip as cut from the sheet and again measuring it after having been hammered between aluminium plates. Differences of potential of considerable amounts were thereby produced.

The temperature is another factor which may play an important part. A rise in temperature causes a large increase of pressure in some cases and a much smaller one in others, and it may even cause a decrease in the value of the single potential.

---

Cleveland as a Center in Electrochemical Development.—We have received a small pamphlet containing a reprint of a recent article by Mr. Cecil L. Saunders in *Electrical World and Engineer*.

The article is a review chiefly of the work done with the electric furnace by the Cowles brothers, although later developments are also mentioned. In a general way, the application of the electric furnace to various metallurgical processes is sketched.

Some historical and personal notes are added. From the data given, it is interesting to note how many of our most successful electrochemical engineers were formerly in some way connected with Cleveland. No detailed technical information is given in the pamphlet on the processes which are mentioned.

## TABLE OF ELECTROCHEMICAL EQUIVALENTS AND THEIR DERIVATIVES.

BY CARL HERING.

In view of the more accurate determinations of the atomic weights and of the electrochemical equivalent of silver which have recently been made, and are now adopted almost universally, the electrochemical equivalents of all the elements which are likely to occur in practice or in experimental research have been recalculated on the above bases under the direction of the writer, and the results are given in the accompanying table, together with many of their derivatives. The table contains not only the data generally given in other tables, but many other elements and valencies in addition, besides a number of new columns which will often be found very useful.

The atomic weights used as a basis are those given in the eighth annual report of the Committee on Atomic Weights of the American Chemical Society, published by the well known authority F. W. Clarke in the journal of that Society for February, 1901. The values are those generally adopted by chemists in this country. They differ but very slightly from the standard values adopted in Germany, many being, in fact, identical. The atomic weights given in this table are for oxygen = 16, and not for hydrogen = 1, as the former are more generally used; but the electrochemical equivalents and their derivatives are, of course, independent of these arbitrary bases, and are therefore exactly the same for both. The only alteration made by the present writer in these values of the atomic weights was to change that of silver from 107.92 to 107.93. The latter conforms with the German table and that of T. W. Richards, and is probably the more accurate; but the chief reason for making this very slight change is that the value 107.93, when taken together with the international standard value of the electrochemical equivalent of silver, 0.001118 grams, gives 96,538.5 coulombs for the ionic charge per unit valent gram ion, and this is in practical agreement with the abbreviated value 96,540, which is so commonly used in all countries. The adoption of 107.93, instead of 107.92, for the atomic weight of silver therefore makes the agreement between some of the different units used by electrochemists almost absolute, and is therefore thought to be justified. As the difference between 107.93 and 107.92 is only 1 100 of 1 per cent., it is, moreover, absolutely negligible in almost all cases.

The other fundamental value used in this table is the electrochemical equivalent of silver, namely, 0.001118 gram per coulomb, which was adopted by the International Electrical Congress, at Chicago, in 1893.

The value of the ionic charge which necessarily results from these two fundamental values is 96,538.5 coulombs per unit-valent gram ion, which is in practical agreement with the abbreviated value 96,540 in common use, the difference involving only unwarranted accuracy.

The column containing the valencies has also been headed "change of valency." The reasons for this will be explained below. It will suffice to say here that the latter term is the rational and more accurate way of stating that which concerns the electrochemist, and it simplifies many of the calculations. Every quantitative calculation of electrolytic action involves a change of valency, or a difference between two valencies, while only certain ones (though perhaps the majority in ordinary practice) involve directly the whole of the valency itself. It is for this reason that this column contains some numbers which may never occur as valencies, but which do occur as changes of valency. For the ordinary and more usual case of the setting free of an element (such as a metal or gas) at the electrodes, the change of valency and the valency itself are the same thing, as the valency of a free element is zero, and in such cases either term is correct. In many cases the equivalents for a change of valency equal to unity have been added, so that those for any other changes of valency may then be easily calculated by mere multiplication or division by a single digit. The formulas at the end of the table give the reduction factors for calculating the electrochemical equivalents and their derivatives for any other atomic weight or changes in valency than those given in the table. For instance, if $n$ is the equivalent given in any one of these columns for a valency $a$, then for a different valency $b$ this number $n$ must be multiplied by either $(a \div b)$ or by $(b \div a)$, as indicated. This is always a very simple calculation, as the valencies are always simple digits. The last line gives the factors with which any of these electrochemical equivalents can be calculated for any element, the atomic weight (for $O = 16$) being represented by $y$ and the valency by $x$.

The last eight columns also give the energy equivalent per volt, from which the energy may be determined directly for any other voltage by merely multiplying or dividing by that voltage. These numbers, of course, can be used equally well with the theoretical as with the actual voltage to calculate the theoretical or the actual energy respectively. The value for the horse-power which was used in the last four columns is 745,050 watts, which is the latest and best value obtainable.

In all cases the reciprocal values are also given, so that every calculation can be made by a multiplication as distinguished from a long division. Many of the values are given to a greater accuracy than would be justified by the original data, as the first two or three left-hand figures suffice for most calculations. The object of this accuracy is to enable new values to be determined by mere proportion for any more accurate or different values of the atomic weights that may be found in the future or may be preferred. The electrochemical equivalents and their derivatives, as given in the table, are exactly correct for the values of the atomic weights there given, excepting, of course, the usual slight inaccuracy of the last right-hand digit. The calculations have been made very carefully to five and six places of figures, and were subsequently checked. It is therefore believed there are no errors. Should, however, any errors be discovered, the writer will be greatly obliged if the correction be sent to this journal, as it is the intention to make this table a standard one.

### APPLICATION OF THE TABLE.

A correct knowledge of what the valencies are is of the utmost importance. The amount of copper deposited per ampère hour from a cuprous solution, for instance, is just twice as great as that from a cupric solution, because the valency is half as great in the former and the amount per ampère hour is inversely proportional to the valency. How to find what the valency is will be described later.

The following examples will serve to illustrate the application of the table; they also serve as typical methods of solving more or less difficult problems involving Faraday's law:

*Simplest Case: Deposition or Solution.*—The valency of any element in its free, uncombined state is assumed to be always zero, hence when an element is set free electrolytically the change of valency which it has undergone is always equal to the whole valency. These are the simplest cases to calculate, and include the majority occurring in ordinary practice, as what one generally desires to know is how much metal, gas, etc., will be set free from its solution or dissolved per ampère hour. In such cases all that is necessary is to find out what the valency of that element is in the electrolyte, then look for it in column 2 of the table, and the desired electrochemical equivalent or derivatives from it will then be found to the right in one of the different columns.

*Example.*—How many grams of silver will be deposited in a silver voltameter by 5 ampère hours? The electrolyte is always nitrate of silver, $AgNO_3$, in which the valency of the silver is 1. In the table after Ag and valency 1, the figure under grams per ampère hour is 4.02, which, multiplied by 5, gives 20.10 grams.

How many pounds of zinc will be consumed (not including local action, of course) in the usual chromic acid battery for 10 available horse-power hours if the available voltage is 1.7?

COPYRIGHT, 1903, BY CARL HERING

(For the atomic weights of the other elements and the full names, see table of valencies below.)

The zinc is dissolved as sulphate, and always has a valency of II. From the table under Zn II, the pounds per horse-power hour for 1 volt (column 12) is 2.00, which, divided by 17 volts, gives 1.18 pounds per horse power hour, and this, multiplied by 10, gives 11.8 pounds. For the theoretical amount of energy, use the theoretical instead of the available voltage.

In the same way the amount of any element set free or dissolved by a given current or amount of energy, or the current or energy required for or given out by the setting free or dissolving of a given amount of any element, may be readily calculated directly from the figures in the table. When calculations involving the energy are made for both of the two electrodes, it must not be forgotten that the voltage measured at the terminals of the cell applies to the sum of both reactions taken together, and not to each one separately. This same voltage is used to calculate the total energy, irrespective of whether the calculation is based on the reaction at the anode or the cathode, and the energies must therefore not be added together when both are involved, as the same energy performs both operations. When the local energy at each electrode is calculated separately, as, for instance, from the thermochemical data, the two energies must, of course, be added to give the total; care must then be taken to add them algebraically, as they may have different signs. In the Daniell cell, for instance, energy is given out at the zinc electrode, but is absorbed at the copper, and the total is therefore the difference.

*Simple Case of Change of Valency.*—In many cases the element is neither set free nor dissolved; it simply changes its valency from one value to another. Such, for instance, is the case in the action of many of the so-called depolarizers, like the peroxide of manganese of the Leclanche cell, the peroxide of lead in the lead accumulator, the chromic acid or nitric acid in the Grove or the Bunsen cells. In such cases, find the valencies before and after the reaction, and the difference will give the change of valency which is to be used in obtaining the equivalents from the table. (The sign of this difference indicates the direction of the current, and is therefore not involved in the numerical values.)

*Example.*—How much manganese is involved in a discharge of 100 ampere hours from a Leclanche cell? In this case $2MnO_2$ changes into $Mn_2O_3$. The valency in the first is IV and in the second III, hence the change is I. The table gives 2.05 grams per ampère hour for Mn, with a change of valency of 1, hence for 100 ampère hours the amount of the element manganese involved is 205 grams. The amount of the peroxide corresponding to this is then found, as usual, by the well known chemical calculation: thus the molecular weight of the peroxide $MnO_2$ is $55 + (2 \times 16) = 87$, and that of the manganese is 55, hence $205 \times (87 \div 55) = 324$ grams $MnO_2$.

Those who do not wish to use this simple method, based on changes of valencies, may obtain the same result by the more lengthy and indirect chemical calculation. In such a case

write out the complete chemical equation, involving the zinc, the manganese and the ammonium chloride. Then calculate electrochemically the amount of zinc involved, as described above, and from this determine by purely chemical calculations the amount of the manganese or peroxide which corresponds to that amount of zinc. This will be illustrated in another example.

*Example Illustrating that the Subscripts May be Ignored.*—How much oxygen will be set free per ampère hour in electrolyzing sulphuric acid, $H_2SO_4$? The change of valency of oxygen is its full valency II, as it is set free; the result is therefore taken directly from the table, namely, 0.30 gram. It will be seen that this does not involve the subscript 4. It will be the same for $H_2O$ where the subscript is 1. The amount set free per ampere hour is a fixed and definite quantity, and is entirely independent of any arbitrary chemical formulas, provided only that the valency be known; and in the case of oxygen it is always II.

Similarly, in the case of cuprous chloride, CuCl, the amount of chlorine set free per ampère hour is the same as in cupric chloride, $CuCl_2$, namely, 1.32 gram per ampère hour, although the subscript is twice as great in the latter case. But the amount of copper deposited per ampère hour is twice as great from the former than from the latter, because the valency is half as great.

*Example Illustrating that Coefficients and Intermediate Reactions Can Be Ignored.*—How much nitric acid will be required in a Bunsen cell for 100 ampère hours, assuming that the nitric acid ($HNO_3$) is all reduced to nitric oxide (NO)? The chemical equation of the complete reaction is

$$3Zn + 3H_2SO_4 + 2HNO_3 = 3ZnSO_4 + 2NO + 4H_2O.$$

It will be noticed that to satisfy this equation there must be three molecules of zinc and only two of nitric acid, and it is very important to include those coefficients in making the purely chemical calculation. In the direct electrochemical calculation, however, these coefficients may be ignored entirely, and, in fact, need not be known at all, as the amount of any element corresponding to an ampère hour is a fixed and definite quantity as given in the table, and is independent of any equations or coefficients like these, the only factor that needs to be known being the change of valency.

Furthermore, in the reaction the zinc is dissolved in sulphuric acid, and the corresponding hydrogen reduces the nitric acid. It thus involves the intermediate reaction of the sulphuric acid. But in the direct electrochemical calculation of the nitric acid this intermediate reaction may also be completely ignored, as the amount of nitric acid reduced per ampere hour is, as said above, a fixed and definite quantity, which is entirely independent of any intermediate reactions, provided only that the change of valency is known.

The amount of nitric acid can therefore be calculated independently of either the coefficients or the consideration of any intermediate reactions that may be involved in the complete chemical equation. It is necessary only to know what it is changed into, so as to be able to find the change of valency. In the nitric acid the valency of the nitrogen is V, and in the nitric oxide it is II; hence the change in III, and, from the table, the amount of nitrogen for this change of valency is 0.1745 grams per ampère hour—that is, 17.45 grams for the 100 ampere hours. From this the amount of the acid is then readily calculated by the usual chemical method, as follows: The atomic weight of N is 14, and of nitric acid $1 + 14 + (16 \times 3) = 63$, therefore $17.5 \times (63 \div 14) = 78.5$ grams of nitric acid.

As stated in the previous examples, this same result may also be determined indirectly by starting with the amount of zinc corresponding to the 100 ampère hours, and then, by means of the above chemical equation, calculating the corresponding amount of nitric acid by plain chemical calculations. The change of valency of the nitrogen need not then be known, but the coefficients and the intermediate reactions must be known.

The amount of zinc per ampère hour, from the table, is 1.22 grams (the valency of zinc being always II), or 122 grams for 100 ampère hours. From the equation, every three atoms of zinc require two molecules of nitric acid; the atomic weight of zinc is 65.4, and the molecular weight of nitric acid is 63. Hence the 122 grams of zinc must be multiplied by $2 \times 63$ and divided by $3 \times 65.4$, which gives 78.4 grams of nitric acid, as before, neglecting the slight inaccuracies due to the abbreviated numbers.

*Example Involving a Change of Sign of the Valency.*—How much sulphur is involved per ampère hour in the oxidation of sulphuretted hydrogen, $H_2S$, into sulphuric acid, $H_2SO_4$? The equation is

$$H_2S + 4H_2O = 4H_2 + H_2SO_4.$$

In all the previous examples illustrating the more usual cases, the valencies of the element had the same sign before and after electrolysis, and their signs need therefore not be considered. In some cases, however, like in the present one, the sign of the valency changes, and therefore becomes very important. In every compound the bonds representing the valency must always add to zero. Those of hydrogen are always +, and of oxygen always —. In $H_2S$, therefore, the S must have two negative bonds (valency—II) to neutralize the two positive bonds of $H_2$; but in $H_2SO_4$ the S has six positive bonds (valency + VI), hence the change of valency is the *algebraic* difference, namely, 8 (the sign of which is of no importance here). The table does not contain this valency, but the result is easily obtained by dividing that for a valency of 1, namely, 1.20 by 8, as the amount per ampère hour decreases in proportion as the valency increases. This gives $1.20 \div 8 = 0.15$ gram of S per ampère hour. A change of sign of the valency from — to + implies oxidation (or perduction), and from + to —, reduction.

As in the previous example, the same result may also be obtained indirectly by starting with the amount of hydrogen liberated, and then calculating by purely chemical methods how much sulphur is involved in that equation. The change of valency or the change of sign need not then be known. From the table, 1 ampère hour sets free 0.0376 gram of hydrogen. From the last half of the above equation, every eight atoms of hydrogen set free correspond to one of sulphur in the $H_2SO_4$ formed. The atomic weight of sulphur is 32, hence $0.0376 \times (32 \div 8) = 0.15$ gram, the same as before.

In the reduction of nitric acid to ammonia in the presence of sulphuric acid, there is also a change of sign in the valency, but in this case from + to —, as it is a reduction. The equation is

$$2(HNO_3) + H_2SO_4 + 2H_2O = (NH_4)_2SO_4 + 4O_2.$$

In the nitric acid the valency of the N is + V, and in the ammonium sulphate is —III; hence the change of valency is 8. Or the calculation may be made indirectly by starting with the amount of oxygen set free, and then calculating by purely chemical methods the corresponding amount of nitrogen or nitric acid involved.

*Example Illustrating a Partial Change of Valency.*—How much nitric acid is required per ampère hour when used as a depolarizer in the Bunsen cell, assuming the nitric acid to be changed into ammonium nitrate? The complete reaction is

$$4Zn + 4H_2SO_4 + 2HNO_3 = 4ZnSO_4 + 3H_2O + NH_4NO_3.$$

The nitrogen in the nitric acid has a valency of +V, and in the $NH_4$ of the ammonium nitrate, —III; hence the change of valency is 8. Part of the nitrogen, however, does not change its valency, but remains as $NO_3$, and is therefore not involved in the electrochemical equivalent, the nitric acid thus performing a double duty. The equation shows that half of the N is involved in the change to $NH_4$, and the other half remains as $NO_3$. The former is calculated electrochemically, as above described, and the amount found must then be doubled in order to get the total.

The same result may be obtained indirectly by starting with the amount of zinc involved per ampère hour, and then calcu-

## LIST OF THE ELEMENTS WITH THEIR SYMBOLS AND PRACTICAL VALENCIES

*(By the word "salts" is meant oxides, sulphides, sulphates, chlorides, chlorates, etc.)*

| Name | Symbol | Atomic Weight | Valencies |
|---|---|---|---|
| Aluminium | Al | 27.1 | Salts +III; aluminates +III. |
| Antimony | Sb | 120.4 | Antimonous salts +III; antimonic salts +V; antimonites +III; antimonates +V; antimonides −III, sometimes −I and −II. |
| Arsenic | As | 75.0 | Arsenious salts +III; arsenic salts +V; arsenites +III; arsenates +V; arsenides −III, sometimes −I and −II. |
| Barium | Ba | 137.40 | Salts +II. |
| Beryllium | Be | 9.1 | Salts +II. (Same element as glucinum.) |
| Bismuth | Bi | 208.1 | Bismuthous salts +III; bismuthic salts and bismuthates +V. |
| Boron | B | 11.0 | Salts +III; borates +III. |
| Bromine | Br | 79.95 | Bromides −I; hypobromites +I; bromates +V. |
| Cadmium | Cd | 112.4 | Salts +II. |
| Cæsium | Cs | 132.9 | Salts +I. |
| Calcium | Ca | 40.1 | Salts +II. |
| Carbon | C | 12.0 | Carbonates +IV; salts usually +IV; in CO +II; hydrocarbons, free valencies −I to −IV. |
| Cerium | Ce | 139.0 | Cerous salts +III; ceric salts +IV. |
| Chlorine | Cl | 35.45 | Chlorides −I; hypochlorites +I; chlorites −III; chlorates +V; perchlorates +VII; monoxide +I; dioxide or peroxide +IV. |
| Chromium | Cr | 52.1 | Chromous salts +II; chromic salts +III; trioxide +VI; chromites +III; chromates or di-chromates +VI. |
| Cobalt | Co | 59.00 | Cobaltous salts +II; cobaltic salts +III. |
| Columbium | Cb | 93.7 | $CbO$ +II; $CbO_2$ +IV; columbic salts and columbates +V. (Same as niobium.) |
| Copper | Cu | 63.6 | Cuprous salts +I; cupric salts+II |
| Didymium | Di | | (See neodymium and praseodymium.) |
| Erbium | Er | 166.0 | Salts +III. |
| Fluorine | F | 19.05 | Fluorides −I; all compounds −I. |
| Gallium | Ga | 70.0 | Salts +III. |
| Germanium | Ge | 72.5 | Germanious salts +II; germanic salts +IV; germanites +II; germanates +IV. |
| Glucinum | Gl | 9.1 | Salts +II. (Same element as beryllium.) |
| Gold | Au | 197.2 | Aurous salts +I; auric salts +III, aurates +III |
| Hydrogen | H | 1.008 | Always +I. |
| Indium | In | 114.0 | Salts +III. |
| Iodine | I | 126.85 | Iodides −I; hypoiodites +I, iodates +V; periodates +VII, iodic oxide +V. |
| Iridium | Ir | 193.1 | Iridous salts +III, iridic salts +IV. |
| Iron | Fe | 55.9 | Ferrous salts +II; ferric salts +III; ferrates +VI. |
| Lanthanum | La | 138.6 | Salts +III. |
| Lead | Pb | 206.92 | Usual salts or plumbic salts +II di-oxide or peroxide and plumbates +IV; sub-oxide +I. |
| Lithium | Li | 7.03 | Salts +I. |
| Magnesium | Mg | 24.3 | Salts +II. |

lating the corresponding amount of nitric acid by purely chemical methods, in compliance with the above equation. In such rare and somewhat complicated cases as this one, this indirect method will no doubt be the safer one to use by those not accustomed to the conception of negative valency or changes of valency.

*Example Illustrating the Exhaustion of the Electrolyte at Both Electrodes.*—How many ampere hours will it take to

extract the lead from a solution of nitrate of lead, $Pb(NO_3)_2$, containing 100 grams of lead, when electrolyzed between platinum electrodes? In this case the solution will be reduced at the cathode, where metallic lead will be deposited, while at the anode it will be oxidized, depositing the peroxide $PbO_2$, thus exhausting the solution of its lead at both electrodes. Nitric acid will be formed, and it is here assumed that it will not redissolve the lead by local action.

The equation is

$$2Pb(NO_3)_2 + 2H_2O = Pb + 4HNO_3 + PbO_2.$$

From this it is seen that an equal quantity of Pb goes out at each electrode simultaneously, hence 50 grams of lead will be deposited on each electrode. From the table, 1 gram will require 0.26 ampère hours, the valency of the lead on the cathode being II; hence $50 \times 0.26 = 13.0$ ampère hours will be required. At the anode, the valency of the lead has changed from II to IV, the change of valency being therefore II, which is the same as at the cathode; hence the amount of lead must be the same at both electrodes.

As in the previous examples, this calculation may be made without a knowledge of the change of valency by calculating the amount of metallic lead deposited on the cathode, and then, by a purely chemical calculation, finding the amount at the anode from the equation. In this case the equation shows at once that the amount of Pb on each electrode is the same.

*Example Illustrating a Deposition on One Electrode and a Change of the Solution at the Oother.*—How much cuprous chloride will be acted upon per ampère hour when electrolyzed between platinum electrodes? At the cathode copper will be deposited, while at the anode the chlorine will "oxidize" (or perduce) the cuprous chloride (CuCl) to cupric chloride ($CuCl_2$); there will therefore be no deposit or gas formed at the anode.

The equation is

$$2CuCl = Cu + CuCl_2.$$

The change of valency of the copper is I, not II, as is more usual; hence the number of grams per ampère hour is found directly from the table under a valency of I. The amount of the cuprous chloride corresponding to this is then calculated chemically, in the usual way, from the formula CuCl. This, however, will give only that reduced at the cathode. At the anode cuprous chloride is chloridized to the cupric, and, as this is, of course, not the same as was reduced at the cathode, it must be added to the other in order to give the total required for that same ampère hour. At the anode, the valency of the copper has changed from I to II, making a change of I, and the amount will therefore be the same as at the cathode; hence the total amount of CuCl will be double the amount corresponding to the copper set free, a fact which is also clearly seen from the coefficient 2 in the equation.

The calculation can also be made chemically from the equation, after having first calculated electrochemically the amount of copper set free at the cathode.

*Example Illustrating the Reduction of One Solution and the Oxidation of Another.*—If the cathode is in the copper sulphate and the platinum anode in ferrous sulphate, copper will be deposited on the cathode and the ferrous sulphate will be oxidized into the ferric sulphate. The formula is

$$CuSO_4 + 2FeSO_4 = Cu + Fe_2(SO_4)_3.$$

The copper has changed its valency from II to O, and the iron from II to III, from which all the quantities can be determined by the use of the table. Or from the Cu set free the other quantities can be calculated from the equation by purely chemical calculations.

*Example Illustrating a Case in Which Nothing is Set Free or Dissolved at Either Electrode.*—If the platinum cathode is in a solution of ferric sulphate and the platinum anode in ferrous sulphate, then at the cathode the ferric sulphate will be reduced to ferrous, and at the anode the ferrous will be oxidized (or perduced) to ferric; no gas or metal will be set free or dissolved at either electrode. Fe ions pass from the solution around the anode to that around the cathode, and $SO_4$ ions pass in the reverse direction. The reaction is as follows:

$Fe_2(SO_4)_3$ (at cathode) + $2FeSO_4$ (at anode) = $2FeSO_4$ (at cathode) + $Fe_2(SO_4)_3$ (at anode).

The valency of the Fe in the ferric state is III and in the ferrous II, hence there is a change of I, from which the electrochemical equivalent is found, in the table, to be 2.08 grams per ampere hour. This means that 2.08 grams of iron in the ferrous state will be oxidized at the anode to the ferric state by one ampère hour, and that 2.08 grams of iron in the ferric state will be reduced to the ferrous state at the cathode.

It is here assumed, of course, that there is always enough of the salt present around each electrode to enable this reaction to take place, otherwise some other reactions will begin, such as the deposition of iron on the cathode (change of valency II) or the evolution of oxygen at the anode. Too strong a current will also be apt to cause other simultaneous reactions. Attention is also called to the fact that the relative velocities of migration of the ions through the diaphragm may affect the relative amounts of the salts found on the two sides of the diaphragm after the passage of the currents, as Faraday's law has nothing to do with that; but the amount of iron oxidized or reduced per ampère hour is, according to Faraday's law, a fixed and definite quantity, found from the table, irrespective of which side of the diaphragm the salt will be found on after the passage of the current.

This is a case in which the method of calculation, based on the change of valency, is far simpler than the older one, based on the chemical equation, for the reason that there is nothing tangible set free or dissolved which could be used as a basis of the calculation, as there was in all the other examples. One cannot use the iron in this case as the basis, because it has two different valencies at the two electrodes, and it would give entirely wrong results to use either of these valencies. There may be various ways of calculating the result without involving the conception of the change of valency, but the simplest one of these seems to be to start with the $SO_4$ ions as a basis and then determine from this, by a chemical calculation, the amount of iron involved in the reaction. This $SO_4$ may be assumed, for the purpose of calculation, to pass from the ferric sulphate to the ferrous sulphate, thereby reducing the former and oxidizing (or perducing) the latter. This compound ion can safely be assumed as the basis of this calculation, because it always has, in sulphates, the same valency, namely, II, and the amount involved per ampère hour, therefore, is a constant in all sulphates. This constant amount may be found from any convenient sulphate, such as sulphuric acid, for instance, $H_2SO_4$, and it will be the same for both the ferric as the ferrous sulphate.

From the table, the amount of hydrogen per ampère hour is 0.0376 grams, and, as the atomic weight of $SO_4$ is 96, and that of $H_2$ is 2.02, the electrochemical equivalent of $SO_4$ is $0.0376 \times (96 \div 2.02) = 1.79$ grams per ampère hour. At the anode, one $SO_4$ combines with two $FeSO_4$ to form one $Fe_2(SO_4)_3$. Therefore, as 2Fe (atomic weight $2 \times 55.9 = 111.8$) corresponds to the addition of 96 of $SO_4$, it follows that $1.79 \times (111.8 \div 96) = 2.08$ grams of iron are involved per ampère hour at the anode, which is the same as was found above in the first and much simpler calculation based on the change of valency of the iron. A similar calculation based on what takes place at the cathode will give precisely the same result, as here, again, 2Fe correspond to one $SO_4$, the only difference being that it is a loss at the cathode, while at the anode it is a gain.

*Similar Example, Involving, in Addition, a Chemical Reaction.*—The cathode is in a solution of chromic acid with sulphuric acid; the platinum anode is in a solution of ferrous sulphate. Nothing is set free or enters at either electrode. The complete equation is

$$2H_2CrO_4 + 6H_2SO_4 + 6FeSO_4 = Cr_2(SO_4)_3 + 8H_2O + 3\,Fe_2(SO_4)_3.$$

The chromic acid will be reduced, which would form a precipitate; but this is soluble in the $H_2SO_4$, forming chromium sulphate. The Cr has changed its valency from VI to III, hence the change of valency is III. At the anode, the ferrous sulphate has changed to the ferric, the iron having changed its valency from II to III. The sulphuric acid has a double function; half of it is electrolyzed, the $SO_4$ going to make the ferric sulphate and the $H_2$ forming water, while the other half acts purely chemically by dissolving the reduced chromic acid, forming chromium sulphate and water. The latter half of the sulphuric acid would therefore not be included in the electrochemical equivalent, but must be added to that found from the table. In such cases it is safest to use the chromium or the iron in the electrochemical calculations, and then calculate the required amount of sulphuric acid from the above chemical equation. It may be of interest to note here that this reaction forms an odd kind of accumulator, in which only the liquids enter into the reaction, the plates themselves remaining completely unchanged.

Here, again, the more complicated method of calculation, based on the chemical equation, might be used, as was shown in the previous problem, taking one $SO_4$ as a basis and calculating the other quantities from it.

HOW TO DETERMINE THE VALENCY.

In order to use this simpler method of change of valency in calculations involving the electrochemical equivalent, it is very necessary, of course, to know what the valencies are. Those who cannot determine these changes in valencies with the assistance indicated below must use the older, indirect and generally more lengthy chemical calculation, after having determined electrochemically the amount of some one convenient quantity in the equation.

It would be difficult, if at all possible, to give complete rules for determining the valencies, nor is it the object to do so here. The simplest way is to get them from the table which follows, and which was kindly prepared for this article by Prof. J. W. Richards. It gives what he calls the "practical valencies;" that is, the actual valency, irrespective of any interpretation involving a structural formula. He also gives their signs. There are others which occur more rarely, and still others about which there is some doubt. In such cases the safest method of calculation is the older one, based on the chemical equation, as was explained in connection with each example.

This table also gives the full names of all the elements in alphabetical order, while the other contains only the more important elements classified in the alphabetical order of their symbols. It also contains the atomic weights (based on O = 16) of all the elements, thus enabling one to calculate (by means of the formulas in the last line of the first table) any of the electrochemical equivalents or their derivatives of the elements not included in the first table.

The following few general rules concerning valencies may often be found useful: The valency expresses the number of bonds uniting an element with others in a compound. These bonds (as far as electrolysis is concerned) are negative and positive. For each negative bond of an element in a compound, there must of necessity be a corresponding positive bond of some other element. Each of these negative bonds corresponds to a charge of —96,540 coulombs (or 26.82 ampère hours) of electricity per uni-valent gram ion, and each positive bond to +96,540 coulombs. A change of valency implies a disappearance or appearance of positive and negative bonds, and hence a passage of electricity corresponding in amount to these charges set free or taken up.

An atom of oxygen is assumed to always have two negative bonds; hydrogen always one positive; chlorine (in chlorides) always one negative; $SO_4$ (in sulphates), always two negative; $NO_3$, always one negative; $ClO_3$, always one negative. In metallic solutions, where the metal is the base, its bonds are positive, while those of the radical are negative. Elements in their uncombined form (as deposited metals or free gases) are assumed to have no bonds. These few rules, together with the rule that all the positive and negative bonds must always add to zero, will enable one to find the valencies in most of the usual electrolytes.

This conception of negative valencies, which makes it possible to apply these rules concerning the change of valency to all cases, appears to have originated with Prof. Otis C. Johnson. He did not, however, apply it to electrochemical calculations. The conception of the change of valency as a basis of electrochemical calculations is the same thing, in different words, as the conception of charges received and given off by the ions at the electrodes, which is so frequently used in connection with the dissociation theory. But the use of the table as above described avoids the lengthy calculation involving the ionic charge 96,540, as this constant is already included in the figures given in the table.

---

## ALUMINIUM AS A REDUCING AGENT IN METALLURGY.

By George P. Scholl.

The fact that metallic aluminium, under proper conditions, reduces many of the other metals from their compounds has been known a long time ago. No less a personage than the illustrious Friedrich Woehler, the discoverer of aluminium, tried, in 1857, to produce chromium from its chloride by means of metallic aluminium, and succeeded in obtaining a chromium-aluminium alloy. Numerous attempts have since been made by various investigators—among them Michel, St. Claire-Deville, the brothers Tissier and last, not least, Messrs. Greene and Wahl in Philadelphia—to utilize this reducing property of aluminium for practical purposes. But the stumbling block in the path of these experimenters was the fact that the reduction only takes place at a high temperature, and when this temperature has been reached it proceeds with explosive violence. It was left to Dr. Hans Goldschmidt,

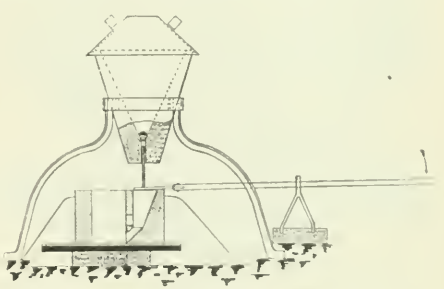

FIG. 1.—SECTIONAL VIEW OF CRUCIBLE ARRANGED FOR TAPPING.

Essen, Germany, to find out the means by which to temper the violence of the reaction and to evolve what is now known as the Goldschmidt process.

In the course of his researches, prompted by the firm of Friedrich Krupp, of Essen, and undertaken with a view to find a process for the manufacture of pure chromium and manganese, he discovered that, in order to have the reaction take place, it was only necessary to start it at one point of the mixture. As the reduction of metallic compounds by aluminium is an exothermic reaction, and takes place with a considerable evolution of heat, the heat liberated at that one point is sufficient to raise the adjacent portions of the mixture to the temperature of reaction, and so on, until the reaction has propagated itself throughout the entire mixture. This, then, was the keynote to a successful application of the aluminium reduction process in practice, but there remained a very serious

problem to be solved yet, namely, to find the best method to start the reaction. After many fruitless attempts, it was finally discovered that substances like the peroxides, chlorates, etc., which easily yield up their oxygen, could be successfully used for this purpose. It requires comparatively little heat to bring them to the point of reaction, and the heat given out thereby is sufficient to start the ignition of the mixture to be reduced. Barium peroxide has been found most satisfactory, and is most generally used.

As a typical example of the method of procedure, it will suffice to describe the reduction of metallic iron from its oxide by means of aluminium. The chemical equation, according to which the reaction takes place, is exceedingly simple, namely, $Fe_2O_3 + 2Al = Al_2O_3 + 2Fe$. The aluminium acts just like

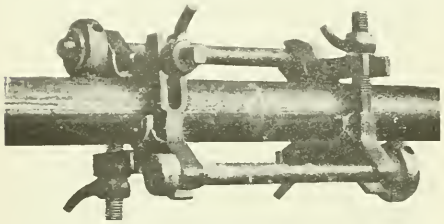

FIG. 2. PIPES CLAMPED TOGETHER BEFORE THE MOLD IS PUT AROUND.

the carbon in the ordinary reduction process, but while the products of combustion in the case of carbon (carbon monoxide and dioxide) are gaseous, the product of combustion in this case is a solid, which, however, becomes fluid through the heat of reaction. The oxide of iron is mixed with powdered aluminium in the right proportion, and introduced into a crucible lined with magnesia or with material obtained from a previous fusion. The mixture cannot be treated in an ordinary crucible, as the alumina, being of a strong basic character, would, at the high temperature developed in the process, immediately combine with the silica of the crucible and destroy it. Ordinarily the mixture would be very hard to ignite, as it can be thrown into an ordinary fire, and even upon molten cast iron, without burning. In order to set off the mixture, a

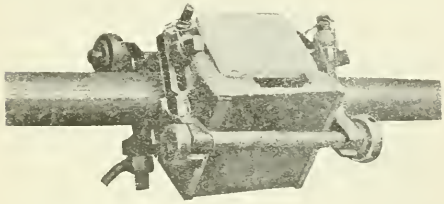

FIG. 3.—HORIZONTAL PIPES WITH MOLD, READY FOR POURING.

small quantity of ignition powder (barium peroxide and powdered aluminium) is put in a small heap on top of the mixture, and is ignited by means of a storm match or by touching it with a red-hot iron rod. The reaction propagates itself quickly through the whole mixture, with the result that in a few seconds the whole charge is a mass of white-hot fluid material. The contents of the crucible have separated into two layers, the molten metal, reduced by the aluminium, being at the bottom and the molten $Al_2O_3$, corundum, above it. That the heat developed during the operation is very great can be seen from the fact that the alumina, the melting point of which lies at about 1,900° C., is liquefied. The temperature of the molten mass in the interior of the crucible has been estimated at 3,000 C. (5,400° F.).

In order to understand the remarkable development of heat in this process, it has to be considered thermo-chemically and a comparison made between the energy density in the crucible and the energy density obtained in other sources of high temperature—for instance, the electric furnace. Starting from the reaction, $Fe_2O_3 + 2Al = Al_2O_3 + 2Fe$, there are required, theoretically, .484 kilograms aluminium for the production of 1 kilogram of metallic iron, furnishing .91 kilograms of alumina. Assuming the heat of combination of 1 kilogram Al to $Al_2O_3$ as 7,140 calories, as determined by Dr. Straus, of Friedrich Krupp, in Essen, there are set free in the above reaction $.484 \times 7{,}140 = 3{,}455.76$ calories. These calories have to furnish the heat necessary for the reduction of the iron, the heating of the iron to its melting point and the heating of the resulting alumina to its melting temperature.

Assuming the average heat necessary for the reduction of Fe from $Fe_2O_3$ as 1,768 calories, 1 kilogram of Fe will require 1,768 calories. If we take the melting point of wrought iron at 1,000° C., the average specific heat of wrought iron between 0 and 1,600° as .19 and the latent heat of fusion as 33 calories, the iron, in order to be melted, requires 337 calories. Finally, taking the melting point of alumina as 1,900° C., its specific heat as .2173 and its latent heat of fusion as 50 calories, we get 425.71 calories required for the melting of the alumina. The balance, therefore, neglecting the loss by radiation, is as follows:

| | | |
|---|---|---|
| Heat generated | | |
| By the reaction of .484 kg aluminium | | 3455.76 cal. |
| Heat required | | |
| For the reduction of 1 kg. $Fe_2O_3$ | 1768 cal. | |
| For the fusion of the metallic iron | 337 " | |
| For the fusion of the alumina | 425.71 " | 2530.71 cal |
| | | 925.05 cal |

There is, therefore, a surplus of heat of 925.05 calories, and, as 1 kilogram of the mixture of oxide of iron and aluminium

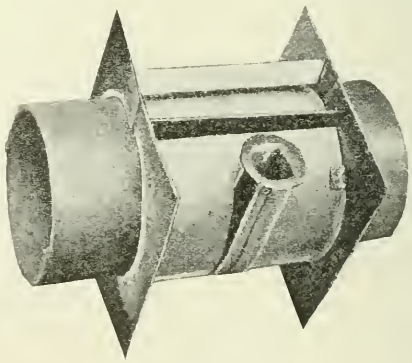

FIG. 4.—MOLD FOR PIPE OVER 5 IN. WIDE.

gives practically ½ kilogram of iron, there are about 450 calories of heat furnished for each kilogram of the mixture. In order to understand why such a relatively small amount of heat could cause the raising of the mixture to such a high temperature as 3,000° C., we must recall the fact that the reaction takes place with great velocity, and that, furthermore, the product is not a gas, as in the case of carbon, for the gasification of which a large amount of the energy has to be expended, but solid, and that the whole energy of the reaction is preserved, as it were, in the crucible.

The average time of reaction of 1 kilogram of the mixture is about one or two seconds, and with large quantities this time is still considerably reduced. Supposing that only 300 calories in one second are developed by the reaction of 10 kilograms of the mixture, the work done would equal $300 \times 425 = 127{,}500$ meter kilograms, or 1,700 horse-power seconds, or 1,149.5 kilowatt seconds, nearly equaling the effect in one second of an arc lamp of 30,000 ampères at 40 volts.

The data given above are taken from a recent paper read by Dr. Goldschmidt before the Society of German Chemists (*Zeitsch. Anorg. Chemie*, 1902, p. 099), where he also gives a comparison between the energy density developed in his process and in the electric furnace, which is of considerable interest to electrochemists. The energy density is calculated in ergs per cubic centimeter. As calculated above, there are available 450 calories for each kilogram of the mixture, and when 10 kilograms react in fifteen seconds, and occupy a space of 3,500 c.c. after the reaction has taken place, there are in 1 c.c. 0.0857 calories = 36.42 mkg. As 1 mkg = 98,100,000 ergs, there are in one second in one c.c. 3,572,802,000 ergs. In an electric furnace like that of Stassano, where the heat is generated by a powerful arc, heating a space of about 1 cubic meter, with an expenditure of energy of 500 horse-power, the energy density is 500 horse-power = 37,500 mkg in 1,000,000 c.c. per second, consequently per second per c.c. 0.0375 mkg. = 3,678,750 ergs, or nearly as 1 to 1,000 as compared with the Goldschmidt crucible. The following table gives a comparison with the energy density of a 500 horse power calcium carbide furnace:

| Time of reaction | Amount of mixture | Volume of the Reaction product | Heat generated | | Energy | | Kind of material treated |
|---|---|---|---|---|---|---|---|
| | | | Total calories | Available calories | Total energy | Available energy | |
| 15 sec. | 10 kg. | 3.5 l. | 4500 cal. = 1890 mkg. | 4500 cal. = 1890 mkg. | 185.4 mkg. = 1818 ergs. | 185.4 mkg. = 1818 ergs. | Calcium carbide |
| 1 hr. | 500 kg. | 175 cbm. | 225000 cal. = 94500 mkg. | 225000 cal. = 94500 mkg. | 9270 mkg. = 90957 ergs. | 9270 mkg. = 90957 ergs. | Calcium carbide |
| 1 hr. | 500 kg. | 175 cbm. | 225000 cal. = 94500 mkg. | 225000 cal. = 94500 mkg. | 9270 mkg. = 90957 ergs. | 9270 mkg. = 90957 ergs. | Calcium carbide |

Of the many applications which the process finds, one of the most important is the production of pure chromium and manganese. Chromium, as is well known, is a most valuable constituent of steel, but until it was made possible to obtain it by the Goldschmidt process it had to be manufactured either in crucible furnaces or in the electric furnace by reducing chrome iron ore with carbon. This, of course, gave not a pure material, but a so-called ferro-chromium, containing about 63 per cent. of chromium and a large amount, up to 12 per cent. of carbon. When this material was introduced into steel, the carbon which it contained added itself to the percentage of carbon already present in the steel. It was therefore impossible to produce a chromium steel low in carbon and at the same time containing an appreciable amount of chromium. The pure metal is now produced by the Goldschmidt process in large and increasing quantities, and finds a number of applications in the manufacture of special steels, as well as in the manufacture of guns, shells and armor plate.

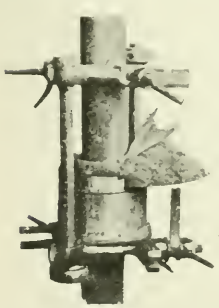

FIG. 5.—MOLD WITH LATERAL POURING FUNNEL FOR VERTICAL PIPES.

The reduction of chromium is very simple, taking place according to the equation $Cr_2O_3 + 2Al = Ae_2O_3 + 2Cr$. The mixture of finely-powdered aluminium and chromic oxide is made in the usual way, and the reaction started by igniting the charge with the ignition powder. The metal in a fused condition collects at the bottom of the crucible, with the corundum slag above it. The process is a strong rival of the electric furnace process for the production of ferro chromium, especially as the latter is not of such uniform composition as regards the carbon as is absolutely necessary where alloys of a definite composition have to be obtained. It is also probable that the process will cut short the efforts to produce pure metallic chromium by electrolysis.

Manganese is also produced of a high degree of purity, up to 99 per cent., the impurities being mostly iron and silicon. It is used to a large extent for copper-bronze and nickel castings. An alloy of 70 per cent. manganese and 30 per cent. chromium is used for the manufacture of special copper alloys, the so called copper manganine. Pure manganese is also used in the steel industry for the production of special steels high in manganese, containing up to 12 per cent. of that metal.

Ferro titanium is another product of the process. The mixture of aluminium with the titanium compound is inflamed by contact with molten cast iron, acting in this way different from the mixture of oxide of iron and aluminium, which is only ignited at the temperature of molten steel. This behavior is made use of for alloying titanium with cast iron by throwing the mixture right on the bath of molten metal. An alloy of ferro titanium is formed with the evolution of considerable heat, which combines directly with the cast iron. The mixture is added in quantities of ½ to 1 per cent., and, within these limits, has a very beneficial effect in making the cast iron finer grained, less brittle and more thinly fluid. In steel castings,

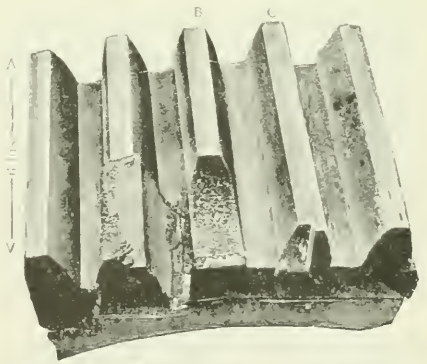

FIG. 6.—SECTION OF A WHEEL FOR REPAIRING.

considerably smaller additions of titanium are sufficient to produce solid castings. The cast iron on which the titanium mixture is thrown has to be sufficiently hot, otherwise the ignition will not take place and some of the metallic aluminium may alloy with the iron, producing unfavorable results.

One of the most interesting of the applications of the process, and probably the most widely used at the present time, is the employment of a mixture of oxide of iron and aluminium, in certain proportions, for welding and repairing purposes. This mixture is called by the inventor "Thermit." Two methods can be used for the welding, the first one depending merely on the utilization of the enormous heat which is developed during the reaction for the heating of the pieces to be welded, and in the second the welding is accomplished by means of the molten, white-hot iron produced. The first one of these methods is chosen where it is desired to weld pipes or pieces of iron together with their butt ends. The butts are fitted well together, and the ends to be welded are cleaned with a file or emery paper. They are then clamped firmly together, and a mold made from strong sheet iron is put around them. In pipes over 5 inches diameter, the pipe has to be completely surrounded by a mantle, with pouring funnel, and a large hole has to be provided for the exit of the air. Pipes can be welded in any position, only the mold has to be

changed to suit the purpose. Several arrangements are illustrated in the accompanying figures. The necessary amount of thermit is then brought to reaction in a crucible, and the contents of the crucible are poured into the mold. When the molten corundum, which flows out first, comes into contact with the cold pipe and the metal of the mold, a layer of chilled corundum forms on them, which cannot be melted any more by the following corundum or molten metal. If the latter would come into contact with the unprotected pipe, it would melt it through at once. The molten mass quickly brings the iron to the welding heat, and then the set screws, which hold the pieces of pipe, are drawn together and the pipes thus pressed closely against each other.

With vertical pipes, the mixture has to be quickly removed, because the ring of metal on the bottom of the mold might stick to them. With horizontal pipes, this is not necessary, and it is better to let the weld cool slowly. Square, round or shaped iron can be welded in the same way. Exact specifications have been prepared for welding pipes from ¾ inch up to 6½ inches diameter, giving amount of thermit necessary, diameter of the mold, etc.

It is important to note that this method of welding is also applicable for coils, which can be welded *in situ* after the parts have been previously bent to the desired form. The welding by this method is of such excellence that the welded part is stronger than the other parts of the pipe. One reason for this is the absolute exclusion of the air during the welding

FIG. 7—RAIL WELDING BY THE GOLDSMITH PROCESS.

process. The welding is, further, absolutely equal in all cases where the same quantity of thermit has been taken, and consequently exactly the same amount of heat has been generated.

The second method, in which the metallic iron produced in the reaction is utilized for uniting the objects to be welded, is carried out in a crucible, shown in cross section in the illustration. The conical crucible has a hole in the bottom, which, during the operation, is closed by a small iron disk, on which is placed a thin layer of fine sand. When the reaction is finished, the small iron disk is pushed up by means of a lever and the contents of the crucible run into the mold. If no layer of sand is put on the iron disk, it will melt through before all the thermite has entered into reaction. The molds have, of course, to be thoroughly dried. The iron produced in the reaction is a very pure wrought iron, specimens showing a composition of C = .10 per cent., Mn = .08 per cent., Si = .09 per cent., S = .03 per cent., P = .04 per cent., Cu = .09 per cent. and Al = .07 per cent. On account of its high temperature, of about 3,000° C., when poured on an object of iron, it softens its surface and welds itself firmly to the object. This method of welding has been used a great deal for welding tramway rails together, in order to avoid the various troubles arising from bad connections between the rails. The rails can be united either by butt-welding them or by simply casting a connection around their ends. The equipment necessary for welding rails is shown in an adjoining figure.

Another important feature of the process is the ease with which it can be applied to carrying out repairs in all kinds of castings. An example of this is shown in the illustration, where the teeth of a gear wheel have been repaired. The tooth on the left shows the repaired tooth before the surface is planed off; the one on the right is partly planed off, and the center tooth is left unrepaired, to show the appearance of the break. It is thus possible to save valuable castings which otherwise would have to go to the scrap heap. The process is also well adapted for the patching up of faulty castings, and, in fact, has such a wide applicability in many instances which are daily encountered in iron foundries and mills that any progressive manager ought to familiarize himself with it. Broken shafting can be welded and repaired in place, and it is stated that even ships' propeller shafts can be repaired at sea, as the apparatus for the purpose is very simple and no large quantities of molten material have to be transported. Instances like this might be multiplied, but they will readily suggest themselves to anyone familiar with foundry and mill work. The increasing application which the process has found in the leading iron and steel works abroad speaks volumes for its practical success.

Altogether, the process is a most interesting one to metallurgists, and has attracted considerable attention. It has not been a haphazard invention, but the result of a painstaking research by a man of broad scientific training, and the inventor has to be congratulated on his success in solving a problem which has baffled experimenters for a long time.

The writer wants to express his thanks to Mr. C. E. Schulz for valuable information on special points in connection with this subject.

## WHY THE E.M.F. OF THE DANIELL CELL CHANGES WITH THE DENSITY OF THE SOLUTIONS.

By Prof. Henry S. Carhart.

In my paper on "A Thermo-Electric Theory of Concentration Cells," read at the Niagara meeting of the American Electrochemical Society, I ventured to give a new explanation of the well-known dependence of the E.M.F. of the Daniell cell on the concentration of the two solutions. The explanation is based on the fact brought out in my paper that the thermo-electromotive force between a metal and a solution of one of its salts increases with the concentration of the solution. The relation between the two is shown in Fig. 4 of my paper, as published in Vol. II of the Transactions of the Society. The thermo-electromotive force is directed from the solution to the metal. Since this is in the opposite direction to the E.M.F. of the cell itself at the zinc electrode, an increase in the thermo-electromotive force at the zinc lowers the E.M.F. of the cell. At the copper electrode, on the other hand, an increase in the thermo-electromotive force increases the E.M.F. of the cell. Now when the concentration of the zinc sulphate solution is increased, the counter E.M.F. of thermal origin at the zinc electrode also increases, and, therefore, the E.M.F. of the cell decreases. Similarly an increase in concentration of the copper sulphate solution increases the thermal E.M.F. at the copper electrode, and this increase adds to the E.M.F. of the cell.

In the October number of this journal Prof. Jos. W. Richards has indirectly called in question my explanation of the phenomenon under discussion by offering another one, namely, the variation in the heat of formation of zinc and copper sulphates, in aqueous solution, with the concentration of the solutions formed. The heat of formation of both sulphates decreases as the concentration increases. The more dilute the solution, the greater the heat of formation. The same relation holds in the case of zinc chloride solution. This fact is brought out in the

classical researches of Jahn, which supported and confirmed the famous Gibbs-Helmholtz equation for the E.M.F. of a voltaic cell. If, therefore, the zinc is dissolved in a more concentrated solution, the formation heat of the zinc salt is less, and the E.M.F. of the cell is diminished. If, on the other hand, the copper is deposited from a more concentrated solution, in which the heat of formation of the copper salt is less, the value of the heat energy transformed in the cell is increased, and its E.M.F. is also increased.

The criticism of Professor Richards has led me to make a few measurements. The results are certainly interesting, and to my mind they are decisive as to the competency of the explanation which I gave in my Society paper. I say "competency," because I do not claim that this explanation excludes others when the subject is approached from a different point of view.

I set up a small Daniell cell of the two-legged variety, connected by small lateral tubes and a short piece of rubber tubing, the same as I have heretofore often used in my measurements of thermo-electromotive forces. In the rubber tube was a short piece of pipe stem to serve as a porous partition. The zinc side of the cell contained first a one-sixteenth normal zinc sulphate solution, and subsequently a normal solution. The E.M.F. was carefully measured in both cases by means of a Wolff's potentiometer or compensation apparatus, and the difference was 0.021 volt at 20° C. The value calculated from the difference in the two thermo-electromotive forces at the zinc surface alone would be somewhat higher. For the 1-16 normal solution the thermo-electromotive force per degree C. is 0.0007 volt; for the normal solution it is 0.0008 volt. The difference multiplied by the absolute temperature gives the calculated value of the variation of the E.M.F. when the one solution is substituted for the other in a Daniell cell. The product is 0.029 volt. The thermal electromotive forces are therefore ample to account for the observed variation in the E.M.F. of the cell. In this calculation I have not taken into account any small thermal E.M.F. at the junction of the two solutions.

The very interesting fact in this connection is that the change in E.M.F. of the Daniell cell when the one zinc sulphate solution is substituted for the other is the same as the E.M.F. of a concentration cell set up with zinc electrodes and the two solutions. A little consideration will serve to show that this should be the case. Suppose two similar Daniell cells set up with the same concentrated copper sulphate solution, one with the 1-16 normal zinc sulphate, and the other with the normal solution. Suppose, further, that the two are connected in opposition. The potential difference would then be the difference in E.M.F. of the two cells. This combination would be like a zinc concentration cell with the two halves connected by a tube containing copper sulphate separated from the zinc sulphate on the two sides by porous partitions. In confirmation of this view, I joined two such Daniell cells in opposition, and added in series with them a zinc sulphate concentration cell set up with the same solutions, 1-16 normal and normal. The concentration cell was turned so that its E.M.F. opposed that of the two Daniells. As anticipated the three cells balanced within 1/1000 volt. A separate measurement of the two Daniells in series and of the concentration cell gave the same result.

Hence, any competent explanation of a simple concentration cell is directly applicable to explain the variation in the E.M.F. of a Daniell cell with a change in concentration of the solutions.

Ideally a concentration cell is one containing no internal chemical energy to be transformed. Such is the case when the solutions are so dilute that they generate no heat when mixed. The heat of dilution is then negligible. The first term in the Gibbs-Helmholtz equation is then also negligible, and the second one, involving the absolute temperature and the temperature co-efficient is the sole expression of the E.M.F. But the temperature co-efficient is the sum of all the thermo-electromotive forces at the several junctions in the cell, all taken with their proper sign. All this rests on the surest experimental facts, and this constitutes the thermo-electric theory of a concentration cell. Such a cell converts heat into electrical energy. In the limit, when there is no internal chemical energy, all the heat is absorbed from the surroundings. On the more dilute side, where the current flows in the opposite direction to the thermo-electromotive force, the heat generated is the combined product of the absolute temperature, the temperature co-efficient or thermo electromotive force at that electrode, and the quantity of electricity passing. On the other side, where the current flows in the same direction as the thermo electromotive force, the heat absorbed is the same combined product; but the latter is larger than the former because the thermo electromotive force is greater. In the measurements which I have made it is enough greater to account for the whole E.M.F. of the cell. Hence the heat of solution must be negligible, or else the necessary heat absorbed comes in part from the dilution. This point is capable of experimental determination by one of the methods used by Jahn in his well known researches.

The explanation applicable to the concentration cell may be carried directly over to the Daniell cell and applied to explain the change of E.M.F. due to a change of concentration.

The foregoing measurements show that for the concentrations used the E.M.F. of the concentration cell is the same as that of the two Daniells in opposition. This result is not in agreement with the conclusion of Nernst that the E.M.F. of the concentration cell is to the difference of the two Daniells as the ionic velocity of the anion is to the sum of the ionic velocities of the anion and the cation. (See Jaeger's *Die Normalelemente*, p. 29).

## TWO GERMAN PLANTS FOR STERILIZING WATER BY OZONE.

The first two German plants in which electrically produced ozone is used as a sterilizing and oxidizing agent in connection with commercial water works, were opened last autumn in Schierstein, near Wiesbaden, and in Paderborn. That ozone is well adapted for water sterilization, being a powerful destroyer of organic matter, both vegetable and animal, is well known and requires no longer proof by practical experiments. But the all important question is whether the cost of this

FIG. 1—OZONIZER ROOM.

method is not prohibitive. This question, however, can be decided only by actual practice on a commercial scale, and for this reason all facts published on commercial plants must be of interest. A method used at two Dutch plants was described in ELECTROCHEMICAL INDUSTRY, September 1902, Vol. I, pages 31 and 32; in these plants the Vosmaer Lafaret system is used. The two German plants which will be described in the following, were installed by the Siemens & Halske Co. of Berlin.

The plant at Schierstein was installed to the order of the

municipal authorities of the city of Wiesbaden, and is designed to sterilize 250 cubic meters (66,000 gallons) of water per hour as a maximum, as stated in recent articles in *Schilling's Jour. f. Gasbel u. Wasserzers*, 1902, No. 40, and in *Zeit. f. Elektrochemie*, 1902, No. 43. But this maximum output is required only for occasions when exceptionally large amounts of water are needed, while in the average only one-half, *i. e.*, 125 cubic meters (33,000 gallons) are sterilized per hour. The other half of the plant serves in general as reserve; the plant is therefore divided into two independent halves, but the apparatus of one half may be worked in connection with the other half, for instance, each set of dynamos may be easily switched over from one-half to the other.

The dynamos installed give current for driving the pumps and also current for the transformers. The transformers are wound for 180 volts primary and 8,000 volts secondary, the secondary windings being connected to the ozonizing apparatus. The ozone produced is then driven by fans into the sterilizing towers, in which the ozone rises upwards and comes into contact with the water flowing down; the water is thus sterilized and flows off into a reservoir.

In the ozonizer room there are 48 ozonizers at both walls of the room, as shown in Fig. 1. As noticed before the whole

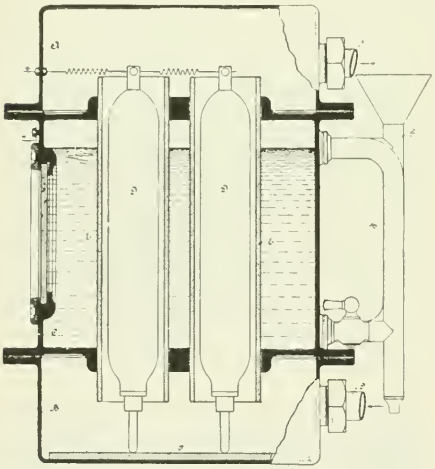

FIG. 2—OZONE APPARATUS.

plant is divided into two separate halves, and each half contains therefore 24 ozonizers; these are divided into three series, each of eight ozonizers, and each such series of eight apparatus is connected to the 8,000-volt secondary winding of a transformer. One such series of eight apparatus gives the ozone required for one sterilization tower. The ozonizers are of the Siemens tube type (glass at the one hand and metal at the other hand), one pole being earthed on account of the method of cooling the discharge surface with water. The ozonizer tubes are shown in Fig. 2, in which A and B are the upper and lower covers, while C is the middle part of the ozonizers. DD are connected to the positive pole, G and H are the tubes for the cooling water, and JJ are the tubes for the air.

The connections to the positive pole (the pole which is not earthed) are well protected, so that it is impossible for the attendants to touch them. Eight ozonizing tubes are contained in an iron box, the upper, lower and front sides of which are provided with thick glass windows. The ozonizer room is generally kept dark, and the attendant who enters it sees at once from the blue light passing through the glass windows of the ozonizer boxes whether the apparatus is working satisfactorily. As all metallic parts connected to the 8,000-volt pole are entirely protected, the attendant can only touch those parts which are connected to the other (earthed) pole, and there is no danger.

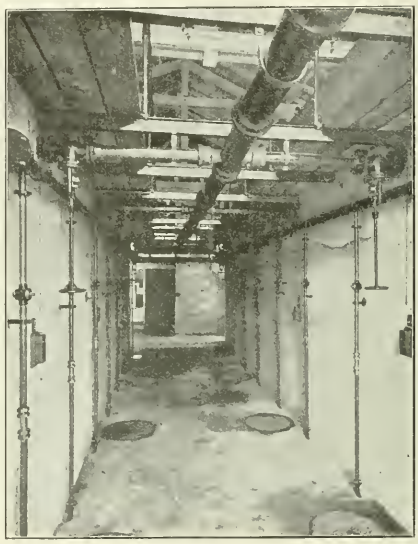

FIG. 3—STERILIZING ROOM.

The sterilizing room which is shown in Fig. 3, contains two series each of four towers of brick. Each tower is divided into four sections by two partition walls perpendicular to one another. A cross section of such a sterilizing tower which is about four meters (13 feet) high, is shown in Fig. 4. As

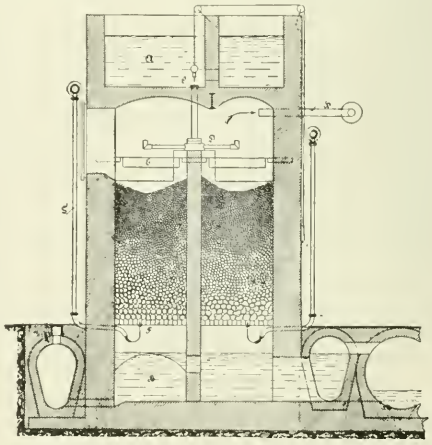

FIG. 4—CROSS SECTION OF A STERILIZING TOWER.

will be seen the tower is filled up to about two meters (6½ feet) with coarse-grained gravel through which the water is trickling down, meeting on its way the uprising ozone current. C is a device for stopping the run of water automatically whenever the operation is interrupted in some way. Through

each full tower (*i. e.*, through its four sections together) 42 cubic meters (11,100 gallons) are flowing downwards per hour, while in the same time 80 cubic meters (2,800 cubic feet) of ozonized air pass upwards. A is the basin containing the not-sterilized water, B the basin containing the sterilized water, EE are screens, G the tube through which the ozonized air is introduced and H the tube through which the air flows off.

Accidents can occur when the operation of the electric apparatus should be interrupted or the introduction of ozonized air to the sterilizing towers should cease, for some reason. Whenever this should happen very simple and reliable automatic devices are provided which prevent a further supply of not-sterilized water to the sterilizing towers.

For the operation of each half of the plant (sterilizing 125 cubic meters or 33,000 gallons of water per hour) 50 horse-power are required, of which 27 horse-power are used for the ozonizers, 22 horse-power for the pumps and 1 horse-power for various purposes.

The cost of the process at Schierstein is 0.35 cent per cubic meter of water, 0.1 cent being the cost of coal required for the operation of the ozonizing apparatus. To this must be added a charge for interest and amortization, which is about 0.15 cent, so that the total cost per cubic meter is 0.5 cent. It is to be considered that at the Schierstein plant power is required for operating pumps which is not necessary for any ordinary ozonizing plant.

Tests of the sterilized water, made by Prof. Proskauer and Dr. Schneider, and also other tests made in the Fresenius Institution, showed that the sterilization process by means of ozone is in every way successful, so far as the results—i. e., the annihilation of germs and bacteria—is concerned. The process is therefore well adapted for the purification of drinking waters.

A month after the Schierstein plant, the Paderborn plant

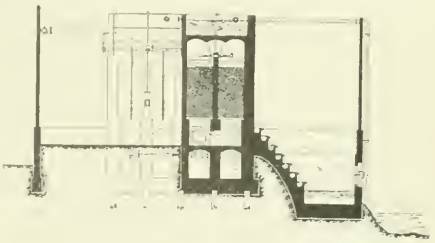

FIG. 5 STERILIZING TOWERS AT PADERBORN.

was opened. Its installation is exactly the same as that of the Schierstein plant, with the only exception of the sterilizing towers. They are illustrated in Fig. 5; the sterilized water is flowing off in form of cascades, so that the ozone dissolved in it is given off. The cost of sterilizing one cubic meter of water is in this plant about 0.4 cent, including charge for interest and amortization.

# SYNOPSIS OF ARTICLES IN OTHER JOURNALS.

*A Summary of Articles on Electrochemistry and Allied Subjects Appearing in American and Foreign Periodicals.*

BY CARL HERING.

## INDUSTRIAL ELECTROCHEMISTRY.

*Conversion of Amorphous Carbon into Graphite.*—Those interested in the artificial production of graphite will find an interesting summary of the systematic work done by various investigators, in a recent paper by FITZGERALD, before the Franklin Institute, and published in the Journal of that society for November. Much work has been done in this direction, notably by Despretz, Berthelot, Moissan and Acheson. By the Acheson process the conversion of amorphous carbon into graphite is complete according to Berthelot's definition of graphite, as that form of carbon which on oxidation at low temperatures yields only graphitic oxide. The density is thereby increased considerably, the mean value of densities of six electrodes before graphitizing being 1.90, and after graphitizing 2.19. The electric conductivity is at the same time greatly increased, Lincoln having found the resistance of one cubic inch of an amorphous carbon electrode to be 0.00124 ohm and that of one cubic inch of graphite electrode 0.00030 ohm, that is about four times the conductivity. The purity of the graphitized carbon is greater than that of the amorphous from which it is made, for a greater or less quantity of the impurities is volatilized, the final purity depending on the temperature to which the carbon has been raised and the time expended in heating. A specimen of anthracite coal was analyzed and found to contain 5.783 per cent of ash. After prolonged heating and conversion into graphite the latter was found to contain only 0.033 per cent of ash. In summarizing the more important work done by the various investigators the author remarks that their results are by no means in agreement. Despretz in his experiments was endeavoring to show that carbon can be fused, welded and volatilized, and thought he had done so. Moissan, however, in his experiments never found any sign of fusion, and concludes that vaporization occurs without previous fusion. In some of his experiments at least, Despretz probably mistook the formation of fusible carbides for fusion of carbon. Despretz's conclusion that any carbon becomes proportionately softer as it is heated for a long time to a high temperature, is incorrect; for instance, the hardness of the ordinary manufactured carbon is increased by prolonged baking at a very high temperature; and some forms of anthracite coal may be so greatly hardened by heating for some time to a high temperature out of contact with air, that they will readily scratch glass. Berthelot's definition of graphite, as given above is perfectly satisfactory from the chemical point of view, but it is not always satisfactory in practice, for example some forms of carbon which come under his definition do not mark paper. The conclusion to be drawn from a comparison of Berthelot's and Acheson's researches seems to be that while all true graphites yield graphitic oxide, all bodies yielding that compound are not necessarily graphites suitable for practical purposes. In view of the fact that various kinds of hard and soft graphites produced by artificial means are now being put on the market, and that varieties of amorphous carbon (notably retort carbon) are also sold under the name of graphite, the author thinks it would be advisable to revise the nomenclature of carbons, reducing it to a more rational and practical form free from all ambiguities. The most interesting of Moissan's methods of transforming amorphous carbon into graphite, as compared with the commercial method, is the conversion by a simple elevation of temperature. While his investigations show clearly that heat has a most distinct effect in bringing about the polymerization of both carbon and graphite, yet, in view of Acheson's work on the remarkable part played by various carbide-forming sub-

resistance in effecting the transformation of amorphous carbon into graphite, some of Moissan's experiments are rigidly conclusive in demonstrating that the change is effected solely by elevation of temperature.—*Jour. Franc. Inst.*, November.

*Electrolytic Alkali Industry.*—To the literature on alkalies J. B. C. Kershaw contributes another article in the Lond. *Elec.* December 12th, which is the conclusion of his former illustrated one. He discusses the electrolytic alkali industry in the United States. He makes brief remarks on some American companies, but seems to give nothing new, nor is his review complete. Some general remarks on the financial conditions of the electrolytic alkali industry and the rivalry of the older Le Blanc process are added. It is said to be proved that a well-equipped Le Blanc alkali plant, using the Deacon process for decomposing its hydrochloric acid, can produce bleach at present at a cost below $17.50 per ton. The fall in the selling price of bleaching powder, while it will seriously curtail the profits of the Le Blanc works, will therefore not cause actual loss to the manufacturer, and therefore continued competition from this quarter must be expected by the electrolytic alkali companies. The author also gives data on the cost of the electrolytic process and finally reaches the conclusion that the total cost of 1 ton of 72 per cent. of caustic soda and 2.1 tons of 35.0 per cent. bleaching powder, by the best electrolytic processes, is about $70. The present selling value of the above amounts of these chemicals is, however, $110, and the 1903 value, when the drop in the value of bleach will have become effective, is $86.25. The prospects of the electrolytic alkali works are therefore not as hopeless as their rivals are disposed to believe; and although some of the companies may fail during the approaching period of competition, it is probable that the stronger ones will survive the ordeal, and that they will be benefited by this trial of strength with the old Le Blanc works.

The Lond. *Elec.*, December 9th, contains an official communication from the electrochemical electrolytic alkali works at Bitterfeld, Germany, to the effect that Kershaw's statement that the Aussig bell process is being used at one of the Bitterfeld works, is wrong.

*Statistical.*—Among the annual statistical information to be expected in this month is an article in the *Eng. and Min. Jour.* January 3d, by Schnattenbeck, on the chemical and allied mineral trades in 1902. In America rapid progress is being made in the manufacture of chemicals, notably those which have heretofore been considered entirely European products. The domestic production of alkali is growing steadily, and as prices are low and the quality of alkali good, imports have fallen over 60 per cent. in two years. Manufacturers of electrolytic caustic soda are proving hard competitors to sellers of the old process article, and imports are suffering severely from this competition. The consumption of bleaching powder is great, as is shown by the large imports and increased domestic production; prices are very low and "in fact, the prices accepted on new contracts are so low that it is impossible for the older works to compete with the modern plants employing electrolytic processes." The domestic consumption of bleaching powder is now about 75,000 or 80,000 tons a year, of which our own works contribute an increasing quantity, while Great Britain and Germany furnish the bulk of the imports. A feature in the trade was the appearance of the new electrolytic bleach made by the Solvay Process Co. of Belgium. Notes are also given on bicarbonate of soda, sal soda, chlorate of potash, chlorine gas, copper sulphate, sulphuric acid, nitric acid, muriatic acid, oxalic acid, carbon dioxide, brimstone, pyrites, alum, copperas, cyanide, cryolite, bromine, barytes, arsenic, zinc dust, bichromates, nitrate of soda, sulphate, ammonia and potash salts.

The same journal contains another by Struthers, on the production of minerals and metals in the United States during 1902. He gives a preliminary statistical table of the output in the United States during 1902. The grand total of the value of metallic and non-metallic substances produced in the United States from domestic ores during 1902, was $1,360,344,147, as compared with $1,198,938,697 in 1901, an increase of 13 per cent. for the year. The total value of metals was $569,149,785, as compared with $496,155,923, an increase of 15 per cent. The value of the production of non-metallic substances was $886,694,362, as compared with $796,411,855, an increase of 12 per cent. The production of aluminum was 7,300,000 pounds, valued at $2,284,590 (against 7,150,000 pounds, and $2,238,590 in 1901). The copper produced in 1902, was 669,855,006 pounds, valued at $78,630,453 (against 609,173,212 pounds and $87,300,515); 358 ounces troy of platinum were produced from domestic ores, and 674 ounces were recovered from South African ores; the quantity of platinum imported during the first eleven months of 1902 was 6,467 pounds (apparently avoirdupois), valued at $1,766,869. The output of zinc was 158,447 short tons, valued at $14,380,650. The output of carborundum was 3,800,000 pounds, valued at $324,058. The output of artificial graphite was 2,351,491 pounds, valued at $111,251. The quantity of sodium salts manufactured in this country was 528,000 tons, valued at $9,477,600. There are also special articles on antimony in 1902; copper, gold and silver, lead, nickel, platinum, tin, zinc, iron and steel, coal, and on progress made in metallurgy at various places.

## THEORETICAL AND EXPERIMENTAL.

*Electrolytic Conductivity.* Judging from the amount of matter recently published on this subject, it has received considerable attention lately, from various standpoints. With reference to theoretical questions, more especially the testing of the validity of the Nernst-Thomson rule, Kahlenberg and Schlundt have recently made some interesting investigations on the solubility, electrolytic conductivity and chemical action in liquid hydrocyanic acid, published in the *Jour. Phys. Chem.* for October. They are of special interest on account of the high dielectric constant of this solvent, thus making possible an exact examination of the Nernst-Thomson rule. The facts are, that while some salts dissolved in liquid HCN conduct electricity better than in water, many others conduct much worse than in their corresponding aqueous solutions. The acids as a class illustrate this in a very striking way; for while their aqueous solutions are most excellent electrolytes, their solutions in liquid HCN are only moderately good electrolytes in the case of hydrochloric and sulphuric acid, while the solutions of the organic acids are exceedingly poor conductors of electricity. In the face of these facts, the Nernst-Thomson rule can not be considered as substantiated by the conductivity of solutions in liquid HCN. The authors conclude that the conductivity of a solution is not determined by the dielectric constant of the solvent, its state of polymerization or its spare valences, but rather by the specific nature of the compound formed when solute and solvent act on each other to form the solution. For instance, the relatively high conductivity of amyl amine, strychnine and morphine in liquid HCN is worthy of note; these bases undoubtedly react with the liquid HCN, forming salts that dissolve in an excess of the solvent.

The influence of the solvent in electrolytic conduction has recently been investigated by Patten, the principal results being as follows: The lowering of the specific electric conductivity of non-aqueous solution by the addition of a pure solvent, is approximately proportional to the number of gram-molecules of solvent added; the application of this principle offers a new method of determining molecular weights. The curves of alteration of the specific electric conductivity are peculiar to each solvent; the alteration depends upon the chemical character of the solvent employed all degrees of this chemical influence of solvent on the original solution, being observed, from water to benzine. The idea is advanced that electrical conductivity is the resultant of, first, the tendency of some molecules to transfer the charge produced by an impressed e. m. f., and, second, the resistance offered to this

transfer of charge by other molecules. Konowalow's conclusion that the small molecular volume of water stands in a definite relation to the power of aqueous solutions to conduct electricity, is unwarranted; also his conclusion that the magnitude of the electrical conductivity of solutions is proportional to the intensity of chemical combination between solvent and solute, as measured by the heat effect. The conduction of electricity by solutions depends upon the fact that a compound is formed by the solvent and solute when solution takes place; and the degree of electrical conductivity depends upon the constituents in this compound, and possibly upon their arrangement. These investigations are described in the *Jour. Phys. Chem.*, November.

The limits of electrolytic conductivity were investigated by BONSFIELD and LOWRY, in a paper in which they point out that, quite apart from the limits due to freezing or boiling, electrolytic conductivity has another lower and an upper limit. At the lower limit the viscosity of the solvent stops the motion of the ions, and at the upper limit the solvent loses its ionizing power. The series of changes may be represented by a curve giving the conductivity as a function of the temperature; this curve has a maximum, depending on the nature of the solvent and solute as well as on the concentration of the solution, the conductivity being a maximum and the temperature co-efficient of the conductivity being zero at this point; as the temperature falls, the conductivity decreases, because the increasing viscosity more than counterbalances the effects of increasing ionization. Over a considerable range the curve follows an approximately linear law, this straight line becoming concave to the horizontal axis at the higher temperatures and convex at the lower temperatures. On this part of the curve the conductivity of the majority of aqueous solutions must be represented, the acids giving values on the concave and the salts on the convex part of the curve. At very low temperature the curve probably becomes asymptotic to the axis of temperature. Above the temperature of maximum conductivity the conductivity also decreases, the decreasing viscosity being now more than counterbalanced by the decreasing ionization of the solution. The decay of ionization becomes more rapid as the temperature rises, and if the solution is not an electrolyte *per se*, the curve runs steadily down and cuts the axis at the critical temperature of the solution. The paper is published in the *Proc Roy Soc.*, October 17th, an abstract of which is given in the Lond. *Elec.*, November 28th.

An account of experiments to determine the conductivity of concentrated solutions of sulphuric acid, caustic soda and calcium chloride, which have very low freezing points, is given by KUNZ in the *Comptes Rendus*, November 10th. With a 45 to 70 per cent. solution of sulphuric acid, temperature below 70° could be attained and measured by means of a constantan iron couple. His measurements show that the conductivities of all of these do not converge to zero (that is, infinite resistance) at —39°, as Kohlrausch supposed, but more likely at absolute zero, thus representing the reverse of the case of the pure metals, whose resistivities converge to zero at the same point. An abstract is given in the Lond. *Elec.*, November 28th.

*Aluminum Anode.*—The curious and somewhat mysterious behavior of aluminum as an anode, in that it stops a current from passing, and may therefore be used as a rectifier of alternating currents, is receiving some much-needed investigation, and the anomalous action is beginning to be more clearly understood. Although much was promised by such rectifiers some years ago, they have not been found practicable with the exception perhaps of the new form described last year by Burgess. Among the recent investigations of this behavior of aluminum is a (Brit.) Physical Society paper by TAYLOR and INGLES, an abstract of which is given in the Lond *Elec.*, November 28th. They begin by calling attention to the fact that aluminum is very slowly acted upon by dilute sulphuric acid even at moderately high temperatures, which with dilute hydrochloric acid the action is violent, and it is found that if a little hydrochloric acid or a soluble chloride be added to dilute sulphuric acid, the action is as violent as with hydrochloric acid of the same concentration. This peculiar phenomenon is thought to be connected with the other well-known fact that when an aluminum electrode is used as anode in a solution of a sulphate or of sulphuric acid, there is a very great resistance which does not exist when the aluminum plate is cathode or when other acids are substituted for the sulphuric acid; this great resistance is generally supposed to be due to an insulating film. The authors endeavor to explain both phenomena as being due to the same cause. They used a cell containing an aluminum and a platinum electrode in dilute sulphuric acid; they examined the influence of the addition of certain salts; the influence of potassium chloride, bromide, nitrate, acetate, chlorate and thiocyanate were thus investigated and the authors conclude that the presence of certain ions enables a large current to pass through the cell. They think the reason is that the film of aluminum hydroxide on the anode is permeable to certain ions but impermeable to others. The anomalous behavior in sulphuric acid would then be due to the impermeability of the film to the negative sulphuric acid radicle ions and also to the positive three-valent Al ions. This explanation is in agreement with the fact that a reversal of the p. d. acting upon the cell immediately causes a current to pass, the film being permeable to hydrogen ions. They made experiments on the rate of diffusion of various ions through a film of aluminum hydroxide, and found that several salts of potassium diffused rapidly through such a film, but the sulphate passed through very slowly. This strengthens the argument that the abnormal behavior of aluminum anodes in sulphuric acid is due to impermeability. It is suggested that the very small current which does pass may be due to a secondary action at the anode in which the ions of water take part. The theory is confirmed by a series of experiments in which the peculiarities of the aluminum anode are reproduced by means of a platinum anode coated with a film of aluminum hydroxide. A further test was applied in the direct measurement of the resistance of a film of aluminum hydroxide to the passage of different ions. Quantitative experiments which the authors have performed on the effect of the presence of different ions on the reaction between aluminum and sulphuric acid, show that this reaction is accelerated considerably by the addition of potassium chloride.

The theory of a rectifier based on this principle is given in a paper by Guthe, published in the *Phys. Rev.* for December. It has already been abstracted in the ELECTROCHEMICAL INDUSTRY for November.

*Depolarization by Potassium Chromate.*—MUELLER continues the description, in the *Zeit. f. Electrochemie*, December 11th, of his researches on the effect of soluble chromates in the electrolysis of aqueous solutions of the halogens, represented by a diminution of the reduction at the cathode. This latter influence may be shown by the following experiment: A 1 per cent. solution of potassium hydrate is saturated with potassium iodate and 200 cc. are put into the cell containing platinum electrodes, the anodic and cathodic department being separated from each other by a diaphragm. The current is regulated so that it is just below the point at which there would be development of hydrogen at the cathode; that is, there is perfect depolarization. If, then, 2 cc. of an aqueous solution containing 10 to 20 grams of potassium chromate in 100 cc. are added to the cathodic department, hydrogen begins to develope at the cathode, and at the same time the voltage at the terminals of the cell increases. This is shown to be due to the formation of a diaphragm of an insoluble chromium compound on the cathode. The increase of the voltage at the terminals is due to the fact that before the formation of the diaphragm there existed a strong depolarizer, but after the diaphragm becomes active, the electrolyte behaves as though no depolarizer was present.

*Residual Currents.*—While it is generally accepted as true

there is a definite minimum e. m. f. required to decompose a certain electrolyte, yet it is a fact that with any electrolyte, no matter how low the applied e. m. f. is, a current is found to pass; it may be small, but is measurable. This is what was called a "Reststrom" by Helmholtz, who worked with an e. m. f. of 1.1 volt and found that a measurable current passed for weeks at a time through an electrolytic cell with platinum electrodes in distilled water or in dilute sulphuric acid. His explanation is that the solution may originally contain dissolved hydrogen, then this hydrogen present at the anode acts as a depolarizer; at the same time an equivalent amount of hydrogen is liberated at the cathode and will either dissolve in the electrolyte or be occluded; although electrolysis takes place, neither of its products appear and the e. m. f. does not have to do the work implied by the decomposition of water into its components; in other words, a current may pass, although the e. m. f. is less than that required for decomposition; the hydrogen freed at the cathode may diffuse through the liquid until it reaches the anode and so by a constant circulation support the current. If, at the start, the solution or the electrodes contain oxygen instead of hydrogen, the reasoning will be analogous. This view of Helmholtz is supported by the fact that if the gases are artificially removed from the original electrolyte, the "residual current" is much smaller. Bigelow has now made very extended experiments in this same direction, the description of which he published in a long paper in the *Jour. Phys. Chem.* for December. These, he claims, show that Helmholtz's explanation cannot represent the whole truth. His experiments were made with platinum electrodes, and from the results he offers the following new theory: A dissolved gas is assumed to be in a condition analogous to a rarefied gas, some of whose molecules Thomson has shown are capable of carrying positive electric charges, other negative ones. The process of solution is assumed to be sufficient to occasion this differentiation. When a charged gas molecule comes in contact with the metal of the electrode, it gives off its charge; the molecule may then be occluded or remain in solution; in the latter case it increases the concentration of the neutral molecules and thus induces a further differentiation into molecules with opposite charge. If a small external e. m. f. is applied there will be a tendency for one electrode to attract positively charged molecules, and for the other to attract negatively charged molecules. Though the charge on the individual molecule is probably the same as that on the ion, the former are present in such small numbers that the total current carried by them is much less than that carried by the ions when the decomposition point is once passed, in fact negligible in all ordinary work. This theory enables one to say that there is a real and definite decomposition point for each pair of ions under given conditions; any current observed before this value is reached, being due to the charged molecules present. Unfortunately he used platinum plates, which have the property of combining with oxygen and hydrogen, and this necessarily limits his conclusions to such plates. Not until a material is used which is absolutely passive, can general conclusions be drawn.

*Formation of Ozone.*—Wakeling has recently investigated the production of ozone by discharges in a closed volume of oxygen. In this case the formation of ozone has a limit which varies with the conditions of the experiment. Besides the ozonizing effect there exists a contrary effect which counterbalances it after a time. Since for the limited duration of the ozonizing process the spontaneous decomposition of the ozone is negligible, it follows that the electric discharge itself must produce the contrary effect. In endeavoring to obtain a measure of both effects, he starts from the assumption that the ozonizing effect is proportional to the number of molecules of oxygen present, while the decomposition is proportional to the number of molecules of ozone present. There is a decided difference between the behavior of a positive discharge and that of a negative discharge; the maximum percentage of ozone is about three times as high for negative as it is for positive discharges. If, after the negative maximum is reached, the mixture is subjected to the positive effluvium, the percentage falls to the positive maximum. The decomposing activity is the same for positive and negative electricity, but the ozonizing action itself is three times higher for negative electricity. The effect of temperature on both discharges is the same. The results are given in the *Ann. d. Phys.*, November 12th, and abstracted in Lond. *Elec.*, December 19th.

*Electrolytic Oxidation of Organic Substances.*—An account of experiments on the electrolysis of formic acid and oxalic acid, also of potassium carborate, is given by Salzer in the *Zeit. f. Elektrochemie*, December 4th. His investigation is only preliminary, but shows the great difference in the reaction and especially in the anodic potential difference, when a bright platinum, as distinguished from a platinized platinum anode, is used.

*Crystallization from an Electrolyte.*—Heyl gives an account of an experimental investigation of this subject in the *Phys. Rev.* for December, in which after failing to find any effect produced by electrostatic stress upon the formation of crystals, he studied the effect produced on an electrolyte carrying a current, but again obtained negative results. Two substances were used, one was copper sulphate in an aqueous solution, and the other mercuric iodide in concentrated hot hydrochloric acid. The passage of the current produces no effect comparable with that produced by the heating of the solution.

*Alloys of Lead, Tin and Bismuth.*—A very long experimental investigation of the alloys of lead, tin and bismuth from the standpoint of the principles of physical chemistry, especially the phase rule, has recently been made by Shepherd. From alloys containing lead, bismuth and tin, he found that the pure tin crystallizes, but often in an unstable, denser form, and that lead and bismuth form two series of solid solutions, in each case with contraction. When the fused alloys are cooled fairly rapidly, the saturation concentrations are not reached. His researches are published in the *Jour. Phys. Chem.*, November.

*Electric Origin of Molecular Attraction.*—An attempt to reduce molecular action to the electron theory, has recently been made by Sutherland, in a paper in the *Phil. Mag.* for December. He starts with the conception of a neutral gaseous molecule, containing positive and a negative electron, and shows that there is a strong contrast with the law of gravitation; the first condition of the electron theory is satisfied by the fact that molecular mass does not enter into the expression for molecular attraction. It may be considered that the two electrons of a molecule like NaCl, when giving the line spectrum of sodium, revolve round one another in a circle of such size that centrifugal force and electric attraction are in equilibrium; perhaps they revolve entirely within the Na atom. An abstract may be seen in the Lond. *Elec.*, December 12th.

*Laboratory for Electrolytic Analysis.*—The first part of an illustrated description of the laboratory for electrolytic analysis of the Electrochemical Institute of Nancy, is given by Richard in *l'Eclairage Elec.*, December 13th.

## PRIMARY AND SECONDARY BATTERIES.

*Storage Batteries.*—The general problem of the storage battery, involving its possibilities and its future, has been the subject of numerous articles during recent years, and while there is a general similarity between them, and while the results of such opinions do not seem to have had any very beneficial effect, other, perhaps, than to discourage the investigation of radically new types, yet the views of recognized authorities are nevertheless of interest, even though the prophecies of experts do not always come true. Stated briefly, the opinions seem to exist that no other type of storage battery will be found than the present lead battery, and that this lead battery is not what is desired. To predict that nothing new will ever be found in a field where there is a possibility of an

infinite number of combinations of an almost infinite number of chemical materials, seems presumptive, and may not the general condemnation of the much abused lead battery be due largely to the fact that we expect more from it than is possible to obtain in practice? Many of the faults found with the lead battery may equally well be applied similarly to human beings; our life is limited and we resent abuse; yet we would not like to admit that we are complete failures.

The latest comments on the storage battery problem are by SWINBURNE, who, in his presidential address to the (Brit.) *Inst. Elec. Eng.*, discusses the problem of their design as follows: He believes that we are practically limited to lead, at any rate in acid cells. The plate which is anode during discharge should not dissolve in the electrolyte, for if it does the deposition and solution will be uneven, and the plate will grow trees and comes to grief. This excludes zinc and iron unless a suitable electrolyte is found. On the other plate an insoluble depolarizer is needed, or else a double fluid cell must be used, involving a porous diaphragm, diffusion and impracticability. Not only must the depolarizer be insoluble, but it must be converted into an insoluble body on discharge. The coating must be a conductor in one state or the other, or there will be no proper contact. In the lead cell there is always enough peroxide and metallic lead in the coating to secure electrical contact though the discharge product is an insulator. The depolarizing coating must be connected to a conducting plate which is not attacked by local action. Lead and silver are the only available metals, and sulphuric and perhaps phosphoric, the only acids, for the nitrate of lead is soluble and hydrochloric acid is decomposed by lead peroxide. Lead is protected by its coating of sulphate or peroxide, as the case may be. "It thus seems as if we were limited almost absolutely to lead and sulphuric acid. It is wonderful that we have the lead cell at all. We owe it to the chance observation of Planté. The theory was not understood for a long time. For many years it was thought that the pressure was due to the $PbO_2$ and Pb, changing into PbO. The acid was merely put in to make the electrolyte conduct, and sulphuric was used because people used it in gas voltmeters, and they never thought that it ought to be as strong as practicable to give the pressure and output. The difficulty of lead sulphate was regarded as a difficulty to overcome." What is wanted in the lead cell, is lightness, large capacity, cheapness, rapid discharge, efficiency and mechanical strength and durability, but these qualities are mostly antagonistic; large capacity means rapid deterioration, mechanical strength means weight, therefore, no use in testing a cell for capacity without testing the efficiency and durability too, published battery reports are often misleading, because they omit essential information. In alkaline cells, although the e. m. f. is smaller, the metals admit of light plates and grids, and the coating may conduct in both states, instead of in only one as in lead cells, so that a larger proportion of the coating may be active. "The future of this type of cell is uncertain, as very little has been published as to results." This part of his address will be found reprinted in the Lond. *Elec.*, December 19th.

*Dry Cells.*—ZACHARIAS, who has written on similar subjects before, believes that the manufacture of dry cells has passed through a state of rapid development in the last two years, especially in the production of very small cells which are very useful for pocket lamps for physicians, travelers, for use in the army, etc. In the ordinary dry cell he claims that not one quarter of the depolarizer is consumed under ordinary circumstances, while in cells of small dimensions the efficiency is better. In general, cells of two sizes are made, the larger one is 70 mm. high and has a cross section of 35 mm. in square; the smaller one is 55 mm. high and has a diameter of 20 mm. Three such cells, sufficiently insulated from each other, are generally put together and surrounded by a card-board cover. The small incandescent lamps are generally provided with a reflector and a lens, and consume 0.25 to 0.3 ampere at 3.5 to 4.0 volts. One cell of the smaller size has driven an electric clock for four weeks, the current being 7 milliamperes. The author urges that in installing electric bells, etc., in houses, the proper dimensions of the wires should be chosen; that is generally not done in practice and much power of the dry cells is wasted. The carbon rods of the small cells are about 6 to 7 mm. thick and the surrounding depolarizing mass has a diameter of 14 to 16 mm.; it is held in position by four small glass tubes, for the sake of proper insulation from the zinc electrode. The distance between depolarizer and zinc electrode is only 1.5 to 2 mm. The electrolyte is to be filled into the space between the zinc and the depolarizer in a thick but easily flowing form, and is afterward made less liquid by special means. Even the best of these small cells, when continually used to light a lamp, last only fifteen minutes, they should therefore be used only momentarily, but notwithstanding this they are very useful for various purposes. His article is in the *Centralbl. f. Accum.*, December 1st and 15th, where he also gives some notes on testing such small dry cells.

## MISCELLANEOUS.

*Capillary Electrometer.*—In many electrochemical researches the voltages to be measured are very low, of the order of one volt or less, and for such low voltages the usual forms of voltmeters are not, as a rule, satisfactory. Moreover they require quite a perceptible current, which is the very thing that one wants to avoid in any electrochemical measurements. The capillary electrometer, therefore, is of special interest for such researches, as it takes no current at all, and its total range is within about one volt.

The following description of a new form by BURCH, abstracted from his Royal Society paper, reprinted in the Lond. *Elec.*, December 19th, will therefore be of interest. Fig.

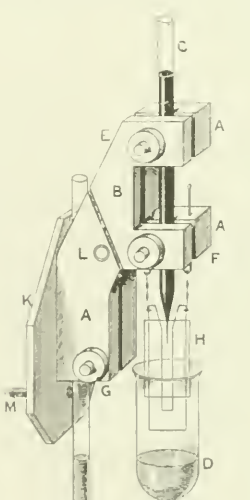

FIG. 1.—CAPILLARY ELECTROMETER.

1 shows the instrument in its final form and Fig. 2 shows the details of the capillary through which is the essential part. The support A is cut from a solid block of ebonite 9 cm. long, 5 cm. wide, and 2 cm. thick; the capillary tube is C. Adjustments for setting the capillary tube at right angles to the optic axis and parallel to the slit of the photographic recording apparatus, are provided for by the stout brass plate K; the screw M fastens it to the adjustable stand of the pro-

rectangular microscope. The brass plate K is so shaped that there is a space of about 3 mm. between it and the left-hand side of the ebonite support A, in order to leave room for the adjustment of the latter about L as a center. The construction of the capillary trough is shown in the diagrams, Fig. 2.

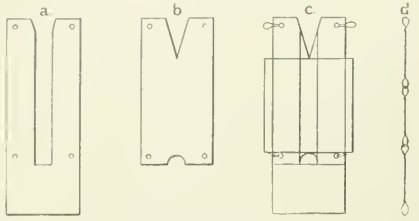

FIG. 2.—CAPILLARY ELECTROMETER.

*a*, *b*, *c*. A piece of mica, such as is used for lamp shades, is cut to the shape *a* with a pair of scissors; four holes are drilled with a needle in the positions shown, and a thin piece of the best clear mica is then selected, the piece *a* placed on it, and four corresponding holes pricked through with the needle, the piece being afterwards cut to the shape *b*. Finally, *a* and *b* are fastened together by four little loops of No. 30 platinum wire, and the whole trimmed to shape with the scissors. The trough is then hung by two platinum chains; these are made of No. 30 wire, with long links, as shown at *d*, Fig. 2, so that the acid may not creep up them; they are hung from the hooks shown in Fig. 1, which are best made of half-round wire, doubled like a linch-pin, sliding easily but firmly in holes on each side of the capillary tube, as shown in Fig. 1. The operation of putting in a capillary is as follows: The instrument is fixed to any convenient support by the screw M; the milled head G is loosened, and the U tube drawn down and turned aside; the whole instrument is then tilted backwards to an angle of 45° from the vertical; in this position the trough H hangs clear of the capillary tube; if the capillary tube has already been filled and connected with the pressure tube, the nuts E and F must be unscrewed far enough for the tubes to pass sideways into the clamps, but a new capillary may be easily and safely inserted from below after merely loosening E and F. It must then be filled to within 2 cm. of the top, but not nearer, with recently distilled mercury from a perfectly clean pipette; it is then connected with the pressure apparatus, and some mercury forced through. The screw M is then slightly loosened, and the instrument raised cautiously to a nearly vertical position. The trough H is adjusted by sliding the hooks up or down, or bending them until the capillary rests against the center of it, the apparatus being tilted back during each alteration. When these adjustments have been made, the inside of the trough is wetted by touching it with a glass rod dipped in dilute sulphuric acid of 25 per cent., and the apparatus is tilted forwards until the wet trough swings against the capillary and sticks to it. A piece of thin cover glass, or mica, if very high powers are to be used, slightly wider than the trough, wetted on one side with the acid, and placed carefully against the trough, to which it adheres, holding it firmly against the capillary, the lower edge of the glass resting against the platinum loops with which the trough is fastened together, as shown in Fig. 2, *c*. The U-tube is then turned back into position, cautiously raised until the lower edge of the glass just dips into the acid, and clamped by the screw G. Finally the trough is gently shaken or pushed to and fro in the plane of the mica, until the acid rises in it to the required height and all the bubbles are expelled. The definition, with these electrometers, is perfect. The capillary touches the cover-glass throughout its length, so that any dry objective can be used. The microscope should not, however, be left focussed on the capillary, lest the acid should by chance get between the objective and the cover-glass.—Lond. *Elec.*, December 19th.

*Sewage Purification.*—An account of experiments made at Salford with various processes of purifying sewage electrically, by Corbett, is given in Lond. *Engineering*, December 26th. The requirements at Salford are governed by the fact that the sewage to be treated is that of a manufacturing town of nearly 250,000 inhabitants, where trade wastes in great variety are admitted to the sewers, and where a large quantity of mere land water enters the sewers also. Among the processes tried was Webster's electrolytic process, and it is said to have been in many points the most unique and most successful of the processes experimented with. Its cost was somewhat high, though by no means the highest considered practicable, and it would have been adopted for the Salford sewage works but for the inability of the company promoting it to finance so large a scheme. In this process no chemical precipitants are used, but "the sewage is passed between cast-iron plates, alternately connected with the positive and negative wires of a dynamo. The effect of this is much like that of chemical precipitants, the sewage being separated into clear liquid and flocculent particles, which subside into sewage sludge in ordinary precipitation tanks." The tank effluent is clear and non-putrescible, but contains fine particles of sesquioxide of iron which give it a rust tint, and this can be readily removed by rapid filtration through a fine sand and gravel filter, the result being a perfectly bright and almost pure filtrate. About half the cost of working is for power to produce the electricity required; this process might therefore be cheap in a place where water-power is available. The company's offer was to treat the Salford sewage for twenty years at $15.06 per million gallons, they providing all the plant, etc., and the plant to be transferred at a valuation at the end of the term. In an appendix the following figures are given concerning this process. The requirements per million gallons of sewage treated per day were as follows: steam engines of 41.76 indicated horse-power; electric horse-power therefrom 33.4; average voltage employed, 41.02; iron used from the electrodes, 428 pounds (this equals about 3.2 grain of iron per gallon).

*Niagara Falls.*—Illustrated articles on the new plant of the Canadian-Niagara Falls Co. are given by Dunlap in the *Sc. Am.*, December 6th, and *Eng. News*, December 11th.

# ANALYSIS OF CURRENT ELECTROCHEMICAL PATENTS.

By George P. Scholl.

ELECTRIC FURNACES AND FURNACE PRODUCTS.

*Electric Furnace.* A. A. Shade, Chicago, Ill. Patent No. 713,923, November 18, 1902. Application filed December 28, 1901.

The specification describes an electric furnace intended for smelting or reducing ores and other fusible substances. It belongs to the type of electric arc furnaces, and the vertical cross section given in Fig. 1 shows three arcs arranged one above another, $D_1D_1$, $D_2D_2$ and $D_3D_3$. The shaft of the furnace is constructed in a peculiar manner, with projecting ledges and corresponding recesses below the electrodes, for the purpose of retarding the fall of the material and exposing it more thoroughly to the heat of the arcs, which are deflected towards the ledges by means of magnets $E_1E_1$. Another magnet $E_2$ is arranged

below the crucible C, so as to deflect the arc between $D_4$, $D_5$ into the crucible. The material is fed into the furnace through hopper $J_2$ and pipe B, and while passing through the conveyer it is dried in the chamber K, which is heated by the waste gases of the furnace, entering through pipe $K_1$. The body of the furnace is surrounded by a metallic casing $A_2$, held together by iron bands A, and the space between the body of the furnace and the casing is filled with insulating material $A_4$, as mineral wool, asbestos, etc. The electrodes are insulated from the casing by insulating rings $A^3$, and are supported in a sliding yoke G. They can be moved forward by means of hand wheel $G_2$ and spindle $G_3$, which bears against a cap fitted to the end of the electrodes. Shields F are provided below the magnets in order to confine the action of the magnets to the arc above them, and to prevent them from influencing the arc below. The crucible C is arranged so that it can be withdrawn from the furnace if necessary. $A^5$, $A^5$ are peep holes between the electrodes and on a level with the respective ledges. $A^1$, $A^1$ are passages in the walls of the furnace,

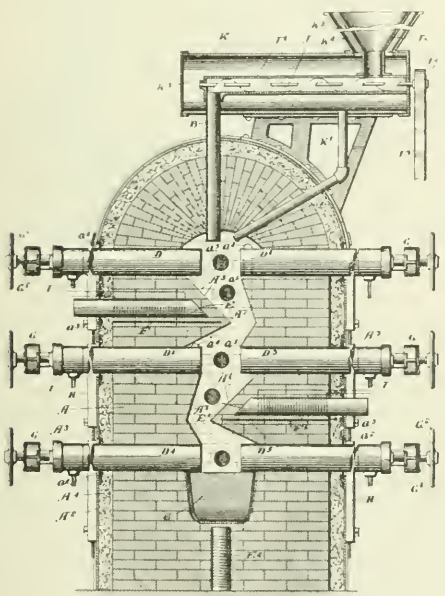

FIG. 1.—SHADE ELECTRIC FURNACE.

intended to permit the furnace gases to pass upwards through the furnace without being required to pass through the arcs.

*Electric Dental Furnace.* A. M. Hewett and J. C. Smith, Chicago, Ill. Patent No. 714,373, November 25, 1902. Application filed February 17, 1902.

The furnace is a portable one, constructed of an outer and inner muffle of fire clay. The inner muffle is provided with a screw thread on the outside, for the purpose of providing a seat for the heating coil.

*Electric Furnace.* H. N. Potter, New Rochelle, N. Y. Patent No. 715,505, December 9, 1902. Application filed November 21, 1901.

This furnace is an improvement on the inventor's former patent, No. 652,640, of June 26, 1900, in which the main source of heat was an electrolytic tube composed of a mixture of dry electrolytes and supplied with terminals for conveying electric current to the tube, which is kept in a state of incandescence by the current after a preliminary heating by external means. The present invention relates to providing means for preventing the current in such a tube from flowing unevenly, by reason of almost unavoidable slight differences in specific resistance of the tube, due to structural, and perhaps chemical, irregularities in the tube material. These difficulties are overcome by notching the tube, or building it up of alternate sections of relatively good and relatively poor conductors, or by imbedding rods of the good conducting material in a jacket of poorer conducting material. The mixture of dry electrolytes referred to above is a mixture of magnesia and alumina, and as poorer conductors, pure magnesia or pure alumina are proposed. The unmixed electrolytes being poorer conductors than the mixtures, the current will pass along the better conducting segments.

*Electric Furnace.* H. N. Potter. Patent No. 715,506, December 9, 1902. Application filed November 21, 1901.

The furnace consists essentially of a single carbon tube, lined with magnesia and coated with the same substance, surrounded again by a jacket of calcium oxide, the whole being then inclosed in a larger tube of glazed stoneware. The specification deals mainly with the mechanical means adopted to meet the problem of the expansion and contraction of the parts of the tube, which are alternately heated and cooled, and for which provision has to be made, on account of the intense heat at which the furnace is to be run. Moreover, as the material proposed for the jacket—namely, calcium oxide—is a hygroscopic substance, subject to slacking, means have to be provided to protect it, which is done by arranging a stuffing ring at or near the air inlet, in such a position that it will absorb moisture from the indrawn air and can be itself rapidly removed if necessary. Other materials of a heat-insulating and refractory nature, such as chalk, asbestos, etc., can be substituted for calcium oxide in the jacket.

*Tubular Electric Furnace.* H. N. Potter, New Rochelle, N. Y. Patent No. 715,507, December 9, 1902. Application filed February 7, 1902.

The same inventor declares in this specification that a carbon tube furnace is subject to sagging or warping out of shape under the influence of extreme heat, the carbon becoming plastic at the high temperature reached in the furnace, while other substances, such as magnesia, which are also used to form the body of such furnaces, are still more subject to distortion of shape under the influence of heat. The means proposed to overcome this difficulty consist in a series of carbon collars surrounding and supporting the internal tube throughout its length, the collars extending from the tube at right angles into a region which is much colder than that next to the tube. The construction does not interfere with the use of a jacket, as described above, as the carbon collars extend into or through the jacket. The whole structure, including the jacket and the collars, is then inclosed in a jacket of non-conducting material, *i. e.*, glazed stoneware, as referred to above.

*Electric Furnace.* H. N. Potter, New Rochelle, N. Y. Patent No. 715,508, December 9, 1902. Application filed March 27, 1902.

The inventor says: "In an application filed by me on November 21, 1901, I show and describe a lined carbon furnace tube, in which the tube rotates about its axis in order that the melted lining material may flow evenly over the inner surface of the carbon tube, while that invention also contemplates the rotation of the furnace tube for other purposes, as when metallic chromium is produced by a continuous operation and the material is worked steadily through the furnace, partly by the effects of the rotation of the tube. The present invention contemplates making the furnace of a double tube." Provision is therefore made to have the main carbon tube stationary and to arrange inside of it a comparatively thin-walled tube, which is to be revolved. By this means it is possible to renew the inner tube very easily. Connections to the main tube are much less complicated than if it rotated, and the space between the two tubes can be filled with an inert gas. The

inner tube may either be of carbon or of a material such as magnesia, zirconia, or the like. For operations such as tempering steel, firing enamel and melting alloys, the advantages of having an inner rotating refractory tube can be secured without the use of the latter by merely having a rotating magnesia lining, the temperature not being sufficiently high to cause the lining to adhere to the carbon furnace walls.

*Lead Support and Circuit Terminal for Carbon Tube Furnace.* H. N. Potter, New Rochelle, N. Y. Patent No. 715,509. Application filed March 28, 1902.

This patent describes improved means for making electrical terminal connections with carbon tube furnaces, and for mounting such furnaces in such a manner as to permit expansion and at the same time provide good mechanical support. The means employed for this purpose are metallic diaphragms at each end of the carbon tube; these diaphragms serving also as parts of the electrical connections at the ends of the furnace tube.

*Process of Obtaining Metallic Aluminium or Other Metals by Electrolysis.* Girolamo Taddei, Turin, Italy. Patent No. 715,625. December 9, 1902. Application filed July 17, 1901.

This invention relates to a process for obtaining metals from their compounds, and particularly the metal aluminium from its oxide, and the object is to effect this with the minimum of energy thermoelectrically considered in relation to industrial conditions, and to effect it in an automatic, or substantially automatic, and continuous sequence of steps or operations. Fused sodium chloride is first decomposed by electrolysis, and its elements are obtained in the form of vapors, the temperature being about 1,000° C. and the voltage about 4.5. The chlorine vapors are then introduced into a vessel charged with balls formed from a mixture of tar and dehydrated alumina, in which the proportions of the ingredients are as 6 of carbon to 9.1 aluminium. This vessel and its contents are heated up to from 1,300° to 1,500° C., and the chlorine, as it is gradually brought in contact with all parts of the mass, produces a reaction, resulting in the formation of aluminium chloride and carbonic oxide, according to the equation $Al_2O_3 + 3C + 6Cl = 2AlCl_3 + 3CO$. The aluminium chloride from this reaction, being in the state of vapor, passes, together with the carbonic oxide, into another vessel, where it comes into contact with the sodium vapor generated by the electrolysis of sodium chloride in the first step of the operation. Here another reaction takes place; the sodium combines with the chlorine of the aluminium chloride and sets free the metallic

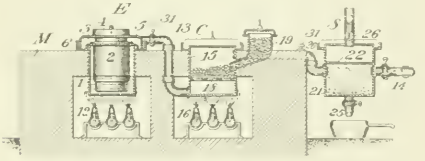

FIG. 2.—SECTION OF ALUMINIUM APPARATUS.

aluminium, $2AlCl_3 + 6Na = 3CO = 6NaCl + 2Al + 3CO$. Thus, says the inventor, the metal aluminium is separated, the sodium chloride is recovered without loss for use again and the carbonic oxide passes off and may be burned. The operations are continuous, the mixture of alumina and tar producing continuously aluminium and carbonic oxide. The sodium and chlorine, separately and in combination, move in a closed circuit without waste or being consumed. The accompanying Fig. 2 gives a longitudinal vertical section of the apparatus in which the process is to be carried out, and Fig. 3 represents the plan. The whole apparatus is set in masonry M, and is divided into three sections, the electrolysis taking place in E, the chlorination in C and the substitution in J. Section E consists of a vessel 1, into which depend separator tubes 2, fixed at their upper ends in an inner cover 3. The carbon anodes 4 depend in these tubes from an upper or outer cover 5, above the cover 3. The edges of the covers rest in a trough 6 around the vessel 1. At the side of the vessel 1, and connecting with it by apertures 7, is a vessel 9 for introducing the electrolyte or making additions during the process. The cathodes are of iron, and situated between the anodes; they are not indicated in the figures. From the space between the covers 3 and 5 two pipes 13 lead to the chlorinating section C, and pipe 14 leads from the interior of vessel 1 to the substituting section S. Section C consists of a vessel 15, divided into two chambers by a transverse partition, each chamber having a false perforated bottom, below which the chlorine enters. Raw material is introduced through hoppers 19, and pipes 20 lead to

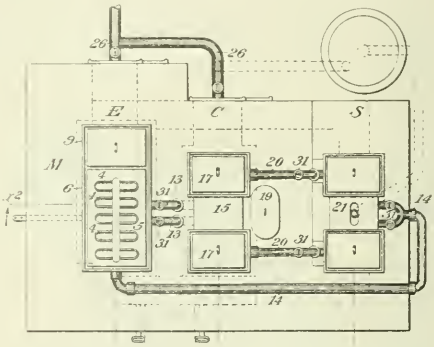

FIG. 3.—PLAN OF ALUMINIUM APPARATUS.

section 5. This section comprises a vessel 21, divided transversely by a partition 22 into two chambers, with covers 23. In each chamber there is also a horizontal partition 24, which extends from partition 22 part way across the chamber. Pipes 20, from vessel 15, and forked pipe 14, from vessel 1, enter below the partition 24. A pipe 26, with forked connection to the chambers in vessel 21, carries off the gases (CO) to the burners 12 and 16. The process is carried out by electrolyzing sodium chloride in vessel 1, the chlorine passing out between the covers 3 and 5 and through pipes 13 into vessel 15. There it acts on the mixture of alumina and tar, and the aluminium chloride and carbonic oxide produced in the reaction pass through pipes 20 into vessel 21, where they meet the sodium vapors conveyed from vessel 1 by pipe 14. Reaction takes place, metallic aluminium and sodium chloride being precipitated, and carbon monoxide escapes through pipe 26 and is led underneath the vessels 1 and 15, where it is burned. In order to separate the aluminium from the sodium chloride, it is proposed to put the mixture into the vessel 9 of section E, where the sodium chloride melts and replenishes the electrolyte, while the aluminium falls to the bottom and may be drawn off. The above process has been outlined at such length on account of the importance which would attach to any new method by which the cost of production of aluminium could be reduced. When it is compared, however, with the simple methods which are in use at present, it does not appear as though such an involved process, with its complicated apparatus, would be likely to accomplish a reduction in the cost of production.

*Apparatus for Obtaining Metals by Electrolysis.* G. Taddei, Turin, Italy. Patent No. 715,626, December 9, 1902. Application filed December 13, 1901.

This patent covers the apparatus used for carrying out the process described above. The wording of the specification is almost exactly the same as that of the preceding one, and nothing new is disclosed as to the nature of the material of which the apparatus is constructed. Anybody who has ever attempted to electrolyze sodium chloride, even at much lower

temperatures than are given by the inventor, knows how quickly metallic, as well as clay and porcelain, vessels are destroyed if they are heated from the outside. Furthermore, it is also well known that the higher the temperature of the electrolyte, the worse the yield of sodium (Borchers, "Electrometallurgie," p. 60).

*Carbophosphide of Calcium.* C. S. Bradley, Avon, N. Y., and R. H. Read and C. B. Jacobs, East Orange, N. J., assignors to the Ampère Electrochemical Co. Patent No. 710,812, December 16, 1902. Application filed April 20, 1898.

The new product described is obtained by heating a mixture of definite proportions of normal calcium phosphate, burnt lime or limestone and carbon in an electric furnace. The ingredients should be well mixed, and, with a mixture of two molecular

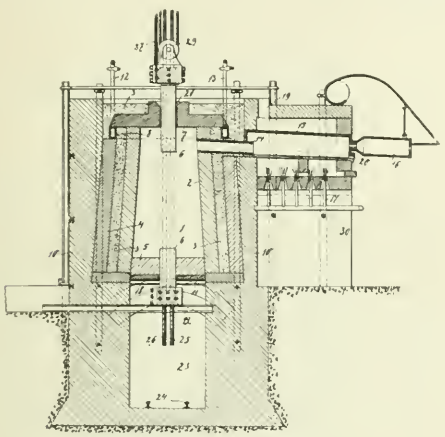

FIG. 4—DORSEMAGEN FURNACE.

equivalents of burnt lime, one of normal calcium phosphate and sixteen of carbon, reaction is stated to take place at the high temperature of the electric furnace, according to the equation $2CaO + Ca_3(PO_4)_2 + 16C = Ca_3C_2P_2 + 10CO$. The material is obtained in a stable, fused mass, which may be tapped from the furnace and allowed to cool, and is described as a homogeneous mixture of carbide and phosphide of calcium, the union of the two materials being analogous to that in the case where two or more metals unite to form a homogeneous alloy. The material, when treated with water, decomposes, yielding a gas which contains acetylene, gaseous phosphide of hydrogen ($PH_3$) and liquid phosphide of hydrogen ($P_2H_4$) or its vapor. The presence of the last body renders the whole mixture spontaneously inflammable, so that if it is thrown into water or brought in contact with a wet surface gases are generated at once and burst into flame. The product is stated to be useful as a weapon of war. For instance, in naval warfare, when it can be projected into the vicinity of the enemy, and on coming in contact with the water a large amount of inflammable gases will be generated, which will at once ignite and force the enemy to retreat.

*Working Zinc and Substances Containing Silicic Acid in Electric Furnaces.* Alfred Dorsemagen, Wesel, Germany. Patent No. 716,008, December 16, 1902. Application filed August 24, 1901.

The inventor of this process has conceived the idea of uniting the production of carbide of silicon (carborundum) with that of metallic zinc by subjecting either naturally occurring siliceous zinc ores, as willemite, or artificial mixtures of roasted zinc ores and arenaceous quartz, mixed in suitable proportions with anthracite coal, to the heat of the electric furnace. In accordance with the equation $Zn_2SiO_4 + 5C = 2Zn_2 + SiC + 5Co$, carborundum is produced, and metallic zinc vapors given off. The operation is carried out in the furnace illustrated in Fig. 4, where 1 designates the furnace shaft, with side walls 2 and bottom 5 of carbon bricks. A layer of very fine sea sand 4 is rammed between the carbon lining 2 and the fire-brick work 4; 6, 6 are the carbon electrodes, between which a core of coke is rammed when the furnace is charged with the ore and coal mixture; 14 in an outlet tube for the zinc vapors; 15 and 16 are condensing chambers for the zinc vapors; 23 denotes a chamber in the bottom of the furnace, intended to accommodate a car, into which the material discharged from the furnace can be received. The process looks as though it was a very expensive one, as far as zinc is concerned, but perhaps the latter is only to be considered as a secondary product, the main product being carborundum. It does not look as though the inventor intended to separate the crystalline from the amorphous carborundum, as Mr. Acheson does, for the furnace does not look as if it was designed to be dismantled after each operation.

*Tap-Hole Plug.* Andrew Dickey, Buffalo, N. Y. Patent No. 714,159, November 25, 1902. Application filed December 2, 1901.

The specification describes a tap-hole plug, especially designed for closing the tapping hole in pots for the reduction of aluminium, where metallic or clay plugs cannot be used, owing to the contamination of the aluminium by the metal of the plug or the silicon of the clay. The plug consists of wood sawdust or paper pulp, either compressed with a suitable binder, like paste or size, or of paper wrapped in layers, the object being to produce a plug of carbonaceous material, such as cellulose, which will, when heated, be converted into a porous, friable charcoal, and which can easily be removed, if desired, without necessitating the use of drilling tools, etc., thus avoiding the danger of injuring the carbon lining of the melting pot. The green plug is placed in the tapping hole, and is converted into charcoal at its inner end by the molten material, but, on account of the low heat conductivity of the material, the carbonization only spreads very slowly to the other parts of the plug.

## APPARATUS AND PROCESSES FOR THE ELECTROLYTIC PRODUCTION OF METALS AND COMPOUNDS.

*Process for Precipitating Metals from Solutions Containing Same.* T. Muffly, Bowdre, Ga. Patent No. 714,590, November 25, 1902. Application filed January 22, 1902.

The object is to provide an improved process for precipitating metals from solutions of alkaline cyanides, bromides, chlorides and hyposulphites or, more particularly speaking, for precipitating gold and silver from solutions of cyanide of potassium, by which said metals have been dissolved out of ores and the like. The novelty of the invention consists in the construction of the electrolytic vessel and of the cathode. The vessel shown in Fig. 5 is divided into two unequal compartments *a* and *b* by a partition *c*. In the compartment *b*, and right against the partition, is placed the anode *e*, of iron platinum, etc. The cathode *j* consists of a cellular porous carbon plate *g*, placed between two cellular porous carbon casings *h* and $h^2$, composed of carbon derived from the destructive distillation of tar, resin, oil etc. Between them is placed a packing *i* of filiform lead and zinc composition, consisting of an alloy of 20 parts of lead to 80 parts of zinc. The carbon plate *g*, casing *h* and $h^2$ and filiform packing *i* are inclosed in a cover $g^2$ of cotton cloth. Between the anode *e* and the

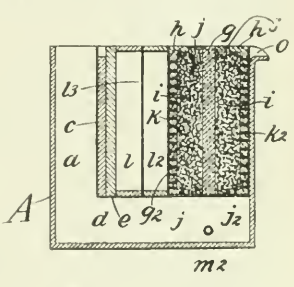

FIG. 5—GOLD DEPOSITION TANK.

cathode *f* is a space inclosed by frames *l* and $l_2$, of glass, porcelain or other non-conductor, and between these frames is preferably placed a screen *F*. Five such boxes are arranged, each having an independent battery of its own, and the electrolyte flows from one to the other. A perforated pipe *i* is arranged under the cathode, by which either hot or cold air is blown into the apparatus. After the electrolysis is finished, the carbon plate *g* and carbon casings *h* and $h^2$ are incinerated, the ashes containing the gold and silver are added to the product of the filiform packing *i* and the product smelted into bullion. The purpose of the glass or porcelain frames *l* and $l_2$ is explained by the inventor as follows "In limiting the electrolytic field between the electrodes *e* and *f* in one compartment *b*, with independent electrical connections with the battery, I secure a more perfect polarization of the solutions. By confining the electrolytic field within the insulating frames *l* and *F*, with the fabric filter screen between them, I prevent floating non-metallic precipitates at the anode *e* from passing through and corroding the cathode *f*, which results in a purer gold and silver product and more effective chemical action. In this method as a whole I secure a perfect and constant polarization of the compound molecules of the solution and a more rapid and complete deposition of the gold and silver atoms at the cathode."

*Apparatus for Separating Metals from Solutions Containing Same.* T. Muffly, Bowdre, Ga. Patent No. 714,598, November 25, 1902. Application filed January 22, 1902.

This specification is nearly identical with the preceding, and claims specifically the apparatus described above.

*Process of Electrolytic Separation of Copper and Nickel.* David H. Browne, Cleveland, Ohio. Patent No. 714,851, December 2, 1902. Application filed January 27, 1899. Renewed September 19, 1902.

The process consists in the electrolysis of a solution of cuprous and nickel chlorides. This is prepared by placing copper-nickel fragments into a long, narrow receptacle and simultaneously subjecting it to the action of a solvent for cuprous chloride, such as salt water, introduced into the top of the aforesaid receptacle, and a stream of chlorine introduced at the side of the receptacle. The chlorine is the product of a later operation. The combined action of the salt water and of the heat produced by the combination of the chlorine with the copper nickel alloy are said to form a solution of cuprous and nickel chloride, which is run into an electrolytic cell. Here it is electrolyzed between copper-nickel anodes and (presumably copper) cathodes. The cuprous chloride is said to be decomposed, the chlorine combining with the copper-nickel alloy of the anode to form cuprous chloride and nickel chloride again. In this manner all the copper is "plated out," and only nickel chloride remains, which is drawn off and freed from iron and traces of copper by precipitation with caustic alkali. The liquor is then heated to a temperature of between 30° and 60° C., concentrated to 30° to 50° Bé, and electrolyzed in a cell with a nickel cathode and a carbon anode, placed in a porous diaphragm. The chlorine given off here is utilized, as mentioned above, for obtaining fresh electrolyte.

*Anode.* F. McDonald, Johnsonburg, Pa. Patent No. 715,684, December 9, 1902. Application filed April 7, 1902.

The invention relates to anodes for electrolytic apparatus designed for the electrolysis of metallic salts, the object being to provide an anode simple of construction and advantageous in widely diffusing the current without undue heating. The anode consists of a tube of glass, or other suitable insulating material, filled with mercury, into which the positive wire is introduced at the top. A number of platinum strips are fused into the lower part of the tube, and it is stated that, in a vessel about 5 feet long, 12 inches wide and 12 inches deep, these strips will be preferably 10 inches long and 2 inches wide. This anode seems to be somewhat expensive for the electrolysis of metallic salts.

*Electrolytic Apparatus.* Joseph Matthews, Kings Heath and William Davies, Selby Park, England. Patent No. 715,281, December 9, 1902. Application filed March 29, 1901.

The apparatus is designed for stripping tin from scrap-tinned metal and depositing it on the cathode. It consists of an outer metallic tank, which at the same time serves as cathode and an inner circular-bottomed tank, insulated from the outer tank. The bottom and sides of the inner tank are formed of perforated insulating material, and the scrap metal, which is introduced in the inner tank and forms the anode, is constantly agitated by the radiating arms of a revolving drum, located in the inner tank. The electrolyte consists of caustic potash and protochloride of tin, heated to a little under the boiling point. Provision is also made for using independent cathodes.

### STORAGE BATTERIES.

*Storage Battery.* S. Laszczynski, Berlin, Germany. Patent No. 714,201, November 25, 1902. Application filed February 23, 1901.

This invention is stated to be an improvement in the construction of zinc-alkali storage batteries. A frame or grate, or any suitable form of electrodes, is pasted with zinc sponge, zinc oxide or zinc combinations in the same manner as with lead-sponge plates. Instead of employing zinc plates for the carrier frame, it may be made of amalgamated iron or nickel plate, or other suitable plate. A number of electrodes thus formed are mounted to alternate with nickel oxide plates, being separated from the latter by a piece of parchment only, the electrode block thus formed being then placed in a receptacle exactly large enough to contain it. As electrolyte, a solution of potassium or sodium aluminates, in which the zinc oxide is insoluble, should be used. Since the electrodes lie very close together, there will be room for comparatively little liquid. As invention is claimed: a storage battery having a negative electrode of nickel oxide, a sponge-zinc plate as positive electrode and as electrolyte a solution of potassium or sodium aluminates, which are able to conduct the current, but not to dissolve the sponge-zinc electrodes after discharging.

*Manufacture of Spongy-Lead Plates for Storage Batteries.* H. W. Butler and J. H. May, London, England. Patent No. 715,016, December 2, 1902. Application filed January 2, 1901.

The invention consists in the employment of powdered carbon (preferably charcoal) in the proportion of 10 per cent., mixed with 90 per cent. of lead oxide as paste or active material for storage-battery plates. The mixture in the above proportions is formed into a paste by the addition of dilute sulphuric acid, and pasted in the ordinary manner on the gird or conducting support of the plate. The plate is then placed in a forming solution, which may consist of dilute sulphuric acid only or dilute sulphuric acid containing a salt rich in oxygen, such as sodium nitrate. It is then connected with the positive pole of a source of electricity, a lead sheet being used as cathode, and the current having a density of about 1 ampère for 100 square inches of plate surface, until the carbon has become sufficiently oxidized, this being indicated by gas liberated from the surface of the plate. If sodium nitrate had been added to the electrolyte a new solution of dilute sulphuric acid must then be provided, and a current is passed in the opposite direction, until the active mass is reduced to spongy lead. The inventors are aware that it has been before proposed to use carbon in the form of small particles added to the paste, and their invention is said to consist "in the subsequent removal (either wholly or partially) of the carbon or equivalent by oxidation by electric action, and then the reduction of the porous mass thus formed to spongy lead by reversal of the electric current."

*Accumulator Electrode.* R. A. Katz, Berlin Germany. Patent No. 715,332, December 9, 1902. Application filed August 21, 1899.

This plate is shown in cross section in Fig. 6, and is built up of a non-conducting frame A in the form of a wide-meshed grating, which forms the support for the active material. It can be formed in one piece out of caoutchouc, celluloid or other acid-proof, non-conducting material. Against the frame A rest two thin perforated lead plates C, one on each face, which cover in the active material, and through their many

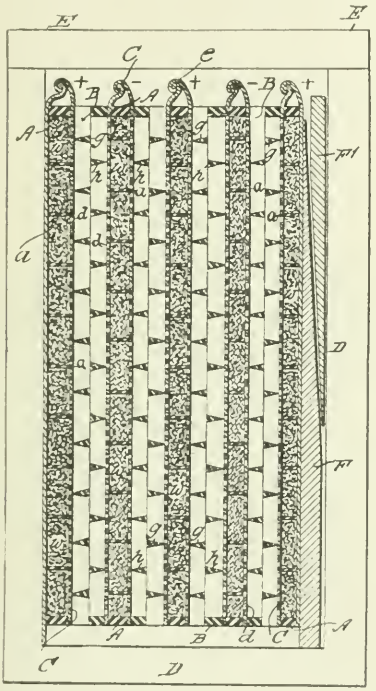

FIG. 6—STORAGE-BATTERY ELECTRODE.

narrow perforations allow access of acid to it. B represents separators, also of non-conducting, acid-proof stiff material, which serve at the same time to afford space for the acid, to keep the positive and the negative plates properly spaced from each other, to press the lead plate against the active material, to assist in supporting the lead plate and, indirectly, also to support the active material. They consist of two superposed gratings *g* and *h*, placed so that the intersections of the one cross the spaces of the other. As advantages are claimed the lightness of the accumulator and the possibility of easily exchanging the lead plates if necessary.

*Accumulator.* F. N. Blanc, Paris, France. Patent No. 715,343, December 9, 1902. Application filed February 17, 1902.

This invention covers a plate made up of a core and frame of aluminium, which are entirely covered with lead. The covering is deposited on the aluminium core by plunging the core, which has previously been provided with a covering of copper by electrolysis, into a bath of molten lead. The covering must be continuous without a break, so as to remove all danger of the attack of the aluminium by the electrolyte. A coating of paste is then applied to both sides of the plate.

*Storage Battery.* L. Paget, New York, N. Y. Patent No. 715,412, December 9, 1902. Application filed September 8, 1899.

The inventor claims that important advantages are secured in storage batteries by the use of a certain silicated material, known as "tufa," as an absorbent material for holding the sulphuric acid or other electrolyte of the battery. He prefers to use a "tufa" obtained from Italy, and has obtained excellent results with "tufa" of probably volcanic origin from the neighborhood of Civita Vecchia. As advantages, he claims the possibility of using an acid of higher specific gravity, a better support for active material of the plates than when "tufa" is not used, and the prevention of fumes in charging a battery, so that a very strong current may be used in charging. He claims that "tufa" remains unchanged, while kieselguhr and pumice stone are liable to break up and form a thin, mud-like material.

*Storage Battery.* L. Paget, New York, N. Y. Patent No. 715,413, December 9, 1902. Application filed August 28, 1901.

This invention "relates to multiple-cell storage batteries—that is, storage batteries formed of two or more cells—the especial object of the invention being to provide a storage battery of large capacity, but of small size and weight in relation to its electrical output. Fig. 7 represents a plan view of such a multiple-cell battery, showing some of the plates in section. A is the cell casing, and is divided into five cells by the insulating partitions B of hard rubber or similar material. The

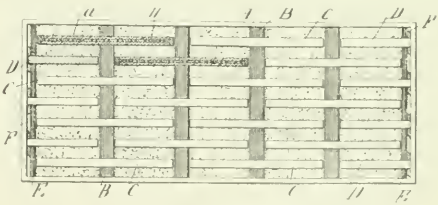

FIG. 7—MULTIPLE CELL BATTERY.

plates are arranged edgewise of the battery and the intermediate electrodes C extend through the partitions B, so that these intermediate electrodes are bipolar electrodes, with the ends of the plates forming the electrodes of opposite polarities. The end electrodes D also extend through insulating plates E at the end of the battery and connect with conducting plates F, provided with lugs for connections. The electrodes are shown as consisting of a supporting non-conducting frame 11, having a perforated web, filled with the active material *a*. Each of the compartments is filled with the electrolyte, which is preferably held or contained by an absorbent material G.

*Storage Battery.* E. J. Knapp, Chicago, Ill. Patent No. 710,056, December 16, 1902. Application filed May 19, 1902.

Buckling in storage batteries usually commences at the corners of the plates, and in order to prevent this triangular corner caps are employed made of substantially-rigid sheet rubber. There is claimed: "A storage-battery plate provided with constraining means at its corner portions for maintaining it in its normal plane against buckling or curling tendencies, the said means being in the form of corner caps."

## GALVANIC CELLS.

*Battery Depolarizer.* C. E. Lockwood and W. C. Banks, New York, N. Y. Patent No. 714,590, November 25, 1902. Application filed September 5, 1900.

The oxide of copper depolarizer used in the ordinary batteries is prepared by oxidizing metallic copper, but as the process of oxidation never goes very deep into the copper, a good deal of it is inactive. The object of this invention has been to avoid the necessity of using this considerable body of useless metallic copper, and the inventors now propose to take

finely divided particles of iron, then plate them with copper and convert the copper into oxide by heating the plated particles in a furnace.

*Gravity Electric Battery.* A. M. Friend, Denver, Colo. Patent No. 715,654. December 9, 1902. Application filed June 8, 1901.

The inventor proposes to overcome various troubles in gravity cells by dividing the cell horizontally into two compartments by a partition adapted to prevent the solid particles of matter from passing from one electrode to the other. The separating risk may consist of pasteboard or other suitable material possessing absorbent or porous property, and is of a size equal to the entire cross-sectional area of the cell.

*Electric Battery.* D. H. Wilson, Chicago, Ill. Patent No. 715,920, December 16, 1902. Application filed April 30, 1902.

The specification describes an improvement in the construction of the zinc carbon cells, by which a greater electrode surface is obtained. The zinc electrode is circular and the carbon electrode is constructed in such a shape that it surrounds, as it were, the zinc electrode on both sides.

MISCELLANEOUS.

*Machine for Washing Matrices Preparatory to Electrotyping.* C. M. Oliver, Baltimore, Md. Patent No. 713,671, November 18, 1902. Application filed August 26, 1902.

The object of the invention is to produce a machine which shall thoroughly and quickly wash away or remove all superfluous particles of black lead or any deleterious substance from the face of the matrix or mold, so that the electrodeposition of the metal on the matrix or mold may be unobstructed and a perfect electrotype copy of the original type-form may be had. For this purpose the inventor puts the molds to be washed face upward on a perforated table, which by means of a suitable mechanism is moved back and forth, while a number of perforated tubes are arranged above it, which spray the mold from all sides as it comes under them.

## CURRENT NOTES.

At the December meeting of the Board of Directors of the American Electrochemical Society, the following applicants were elected to membership: Dr. Leonard Paget, New York; Prof. Dr. Julius Wagner, Leipzig, Germany; R. W. Vicarey, Stafford, England; Prof. Philippe A. Guye, Geneva, Switzerland; Leonard Wilson, Pittsfield, Mass.; Dr. William Dreyfus, New York; Charles J. Pretzfeld, Niagara Falls, N. Y.; August Eimer, New York; Dr. John Shields, London, England; Prof. D. McIntosh, Montreal, Canada; Dr. J. W. Walker, Montreal, Canada; Walter S. Landis, Bethlehem, Pa.; George P. Adamson, Easton, Pa.; Victor Engelhardt, Vienna, Austria; Dr. F. J. Machalske, Long Island City, N. Y.

The American Institute of Electrical Engineers has extended a cordial invitation to the members of the American Electrochemical Society, to attend the Institute meeting on Friday, April 17th; it will be remembered that the annual session of the Electrochemical Society will be held at New York City from April 16th to 18th. At the Institute meeting Mr. Wm. J. Hammer, of New York, will present a paper, illustrated by experiments and exhibits, on the subject of radio-activity and rays in general. Mr. Hammer recently visited Prof. Finsen's Institute at Copenhagen and made an investigation of his treatment of disease by ultra-violet rays; he also investigated the work being done by Prof. and Mrs. Curie at the Curie laboratory in Paris, and some important work that is being done in connection with the properties and applications of selenium. The full title of Mr Hammer's paper is: "Notes on Radium and other Radio-active Substances, and a Consideration of Certain Phosphorescent and Fluorescent Substances;" "The Properties and Applications of Selenium;" "The Treatment of Disease by the Ultra-Violet Rays at the Finsen Institute, Copenhagen."

*Making Steel in the Electric Furnace.*—Just as we are going to press information reaches us that a test of new electric process of making steel has just been made in Lockport, N. Y. Among the gentlemen who are said to have witnessed the test, L. R. Wellman, of Cleveland, and John Fritz, of Bethlehem, are mentioned. The following claim is made: "The process saves 33 per cent. in fuel and nine-tenths in power."

*Susquehanna River Power Plant.*—A newspaper report states that "by the recent formal severance of the street railway system and the electric-light business of Baltimore, the initial step was taken in the $10,000,000 project of developing the water-power of the Susquehanna River and transmitting the same to Baltimore, Philadelphia and Wilmington." The power development of the Susquehanna River is watched with interest also in electrochemical and metallurgical circles.

## CORRESPONDENCE.

### FARADAY'S LAW AND THE THEORY OF ELECTRONS.

*To the Editor of Electrochemical Industry.*

Sir:—The article which appeared under the above title in the November issue of this magazine deserves commendation. Every effort to present in simple form the conclusions of scientific investigation is valuable to scientists in the factory, as well as to those in the university. In the writer's opinion, however, the law of Faraday may be explained in a manner still more simple than that of the article referred to. During recent years, as we are all aware, the general attitude toward the valence theory (better, "hypothesis") has undergone a change. Much as we realize its value to synthetical chemistry, we must admit that in the majority of cases constancy of valence is out of the question, and the reality of bonds is purely hypothetical. It is hoped that the following paragraphs will demonstrate the possibility of understanding Faraday's law without referring to the valence of individual elements and positive and negative bonds.

*Faraday's Law.*—A very satisfactory statement of this law is that made by Professor Nernst: "From the most diverse solutions the same amount of current liberates chemically equivalent amounts of the different ions." The amount of current is measurable, and experience tells us what the ions are; it only remains to determine what are chemically equivalent amounts of the different ions. The unit of comparison of the ions is the hydrogen ion. Any ion which carries the same charge as the hydrogen ion is equivalent to it; its valence is one. An ion carrying double the unit charge has a valence of two, etc. The determination of the number of unit charges carried by an ion (valence of the ion) is particularly simple, because of the close relation between acids, bases and salts, and is readily made clear.

In the solution of an electrolyte, the sums of all the positive and all the negative amounts of electricity must be equal, for the solution acts as electrically neutral. In a solution of hydrochloric acid (an *acid*), the total positive charge of the H ions must be numerically equal to the total negative charge of the Cl ions, and, since the same number of both ions are present, each Cl ion must carry an individual charge equal, but opposite in sign, to that of an H ion. In a sulphuric acid solution, however, the $SO_4$ ion must possess as much negative electricity as *two* H ions positive electricity, for the $SO_4$ ion is in combination with two H ions. In a CuCl solution (*salt*), the Cu ion replaces the H ion of the acid (HCl), and must bear a charge equal to that of an H ion and equal, but opposite, to that of the Cl ion. In a $CuSO_4$ solution, the Cu ion has replaced two H ions; the Cu ion here must carry a charge double that of the H ion. A *base*, e. g., NaOH, is referred to water, the hydroxide of hydrogen; the Na takes the place of

one H of the water, and the Na ion (as well as the OH ion) must carry a unit charge; it is univalent.

In the light of the above, *the number of unit charges carried by an ion is called the valence of that ion, and is equal to the number of hydrogen ions it is in combination with or takes the place of in the given electrolyte.* A gram ion (ionic weight in grams) of a bivalent ion is equivalent to two gram ions of a univalent ion. The same amount of electricity which discharges a gram ion of hydrogen will discharge only half a gram ion of a bivalent ion, or, in general, the ionic weight in grams, divided by the valence of the ion, is equivalent to one gram of hydrogen. Since one coulomb liberates .0104 mg. H, the number of milligrams of any ion liberated by one coulomb is .0104 multiplied by the ionic weight (H = 1) and divided by the ionic valence.

*Theory of Electrons.*—As for this recent theory of Nernst, its connection with the foregoing becomes at once clear when we are told that "electron" amounts to the same as "unit charge," viz.: that which makes an atom or group an ion. The valence of an ion may therefore be expressed in electrons, as well as in unit charges. H. C. COOPER.

Syracuse University.

## Book Reviews.

THE POTASH SALTS: THEIR PRODUCTION AND APPLICATION TO AGRICULTURE, INDUSTRY AND HORTICULTURE. By Dr. Lorentz Albert Groth, with a preface by Samuel Rideal, D.Sc. Lond., F.I.C. London: The Lombard Press, Ltd. 291 pages, illustrated.

This book is devoted to the description of potash salts, the methods by which they are obtained and prepared for the market and their application in the industries.

In the preface Dr. Rideal summarizes the general uses to which potash salts are placed in Great Britain. He calls attention to the pessimistic prophecy of Sir William Crookes in regard to the probable wheat famine of the world, and also calls attention to the renowned experiments carried on at Rothamsted. He finds that the consumption of potash in Ireland is very low, although this potash fertilizer is especially adapted to the potato, which is one of Ireland's chief agricultural products.

In regard to the salts of potash, this book treats of the supply in Canada, and shows that the quantity exported as hardwood ashes is continually decreasing, having amounted to 2,160 barrels in 1804 and only 1,323 barrels in 1808. In France about 2,000 tons of commercial potassium chloride is produced annually by the evaporation of sea water. India furnished about 20,000 tons of nitrate of potash, and about 1,200 tons of potash salts came from the mines at Kalusz in Galicia, the only potash mine in operation outside of Germany.

The historical sketch of the discovery of the natural potash salts is interesting, and shows that as early as 1852 the existence of these minerals was known, but their nature was unknown. The actual working of the mines for commercial purposes began in 1857. There are about 20 mines in all in operation. The dividends paid on the capital shares of the mines are apparently very satisfactory, ranging from 7 per cent., the lowest, to 17 per cent., the highest. The value of the output of the mines for 1902, based upon experience of previous years, is, in round numbers, $8,000,000.

Detailed descriptions of the operations of the mines, with sectional drawings and half-tone portraits of the machinery employed in the mines and in the purification of the salts, are interesting features of the book. A detailed description of all the different characteristics of salt mining is also given. A discussion of the geographical conditions which have made these deposits possible is also an interesting feature of the work. The potash salts are also discussed from a mineralogical point of view, the principal minerals found in the deposits being carnallite, sylvine, kainite, schoenite or pikromerite, polyhalite and kieserite. The different minerals are discussed in detail, both from a mineralogical and chemical point of view. A discussion is also given of the German Potash Syndicate, who practically control the output.

In metric tons, the total output of the mines for 1900 was as follows:

| | Tons |
|---|---|
| Carnallite | 1,607,803 |
| Rock kieserite | 2,047 |
| Sylvinite | 147,791 |
| Kainite | 1,189,394 |
| Total | 3,937,035 |

The amount of carnallite and rock kieserite used directly for agricultural purposes during the past year amounted to 55,489 tons in Germany, and in other countries 2,860 tons. For manufacturing concentrated salts, 1,641,493 tons were used. The amount of kainite and sylvinite used directly for agricultural purposes in Germany was 724,624 tons, and in all other countries 375,007 tons. For manufacturing concentrated salts, 237,554 tons were used, making a total of 1,337,185 tons.

In the potash mines are employed about 7,000 miners, and over 9,000 laborers are employed in the chemical works connected with them. The scientific corps numbers about 300 men. The works are supplied with 642 steam boilers, representing about 66,564 horse-power, and 924 steam engines, representing 59,420 horse-power. Attention is called to the fact that the formation of a syndicate has enormously increased the magnitude of the business and reduced the price of potash to Germans, while outside countries have been compelled to pay abnormally high prices in order to obtain their requirements. The great disadvantage arising out of such a procedure towards foreign agriculture and industry are apparent.

The part of the book devoted to the description of potash salts in industry is fully illustrated, and detailed descriptions are given of the chemical processes by which pure salts are obtained from the crude products. The electrochemical part of the industry is especially well developed. Attention is called to the fact that the history of electrochemistry began with Volta's great discovery, and attention is also called to the prophetic utterance of Davy, in 1806, when he said: "It is not improbable that the electrodecomposition of neutral salts, in different cases, may admit of economical uses." The output of the potash mines of Germany is closely associated with the electrolytic industry applying to salt, magnesium and the alkali and chlorine industry. The application of the electrolytic processes to these industries is briefly described.

From an agricultural point of view, the most important part of the work begins on page 117, with a description of the application of potash salts in agriculture. The consumption of pure potash ($K_2O$) for agricultural purposes is largest in Germany, amounting, in 1900, to 117,712 tons. The United States comes next in the magnitude of consumption, with 65,505 tons. France uses only 8,229, and Great Britain only a little over 7,200 tons. Portugal comes last on the list, with an annual consumption of 43 tons. In amount of potash ($K_2O$) consumed per 100 acres of land under cultivation, the consumption in Germany amounts to 298 pounds; in Holland to 312 pounds; in the United States of America to 42.2 pounds. Thus, while the United States comes next to Germany in the total amount consumed, by reason of the large area under cultivation, the amount per 100 acres consumed in this country is not a very high figure.

Detailed accounts of experiments with potash salts, taken from different authorities, are recorded.

The work is one of great value to the agricultural and technical student by reason of detailed study of the sources and methods of distribution of potash salts and the descriptions of technical processes, and especially on account of the statistics, which are difficult to obtain in the scattered form in which they have heretofore existed. The book will therefore be found useful to the chemist, the engineer and the farmer.

## A NEW ACETYLENE TABLE LAMP.

The excellence of the acetylene light *per se* is so unquestionable that nobody can deny for a moment its enormous commercial possibilities, especially for certain purposes and for certain sections of the country where gas light and electric light are less convenient or entirely out of question. The all important commercial problem for the acetylene lamp manufacturer is at present to convince the general public that acetylene lighting is safe, and that the annoyances and accidents, formerly recorded in connection with the use of acetylene light, are not inherent in the use of acetylene, but were due to the use of inferior apparatus. The whole trouble was that the calcium carbide and acetylene industries developed too rapidly; attracted by the apparent simplicity of the problem, many incompetent inventors designed unsuitable and dangerous apparatus, with the result that the accidents which were due to poor designs and bad construction, were attributed by the public to the use of acetylene itself.

It is very gratifying to state that the conditions of the acetylene industry were very materially improved in recent years by the steady and painstaking work done by the competent engineers of this new industry. The problems involved in the use of acetylene light are now understood, and acetylene lamps are now made in accordance with scientific principles; as a result a steady and healthy growth of the industry is to be recorded. In the following we describe the most recent type of acetylene lamp made by Edward Miller & Co., of Meriden, Conn., for the Electrolite Gas Lamp Co. of New York City, by license under the Beck patents. One of the adjoining illustrations is a sectional cut, showing clearly all details of the design of the lamp; the other sketch shows the lamp separated for filling.

While at first sight of the sectional cut the lamp may look complicated, the operating parts are very few and simple. The lamp consists of three chambers, namely, a water chamber below, a carbide chamber above, and a movable gas holder which operates to bring the carbide into the water. The movable gas holder consists of a rubber bag and is fastened on the top wall of the carbide chamber. To this movable holder is fastened rigidly a feed stem which moves with the top wall of the gas holder and opens the feed when the gas holder is nearly empty and shuts off the feed when it is filled with gas.

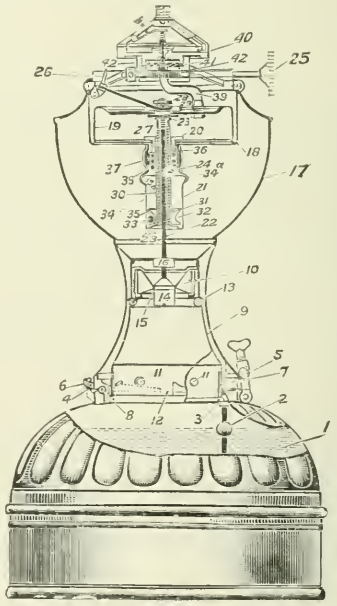
The gas in the lamp varies in pressure. Immediately before carbide is fed the pressure is less and as the carbide falls the pressure is raised slightly by the additional gas generated. The regulator or governor on the top of the lamp on to which the burner is fastened is an auxiliary means for keeping the flame uniform. It has absolutely nothing to do with the generation of gas. In the carbide chamber is located an auxiliary device named the "safety lock," which also has nothing to do with the operating of the lamp. Its function is to prevent further feeding when the lamp is tipped over so that the water cannot enter into the carbide chamber. It automatically arrests the further movement of the feed valve when the lamp is on its side, but permits the free movement thereof when the lamp is upright.

The gas after it is generated passes through the same opening through which the carbide falls and is dried by passing through the carbide and then screened by the felt filter. The mechanism in the top of the lamp over the gas bag is for the purpose of manually arresting the feed. When spindle 25 is turned inward the feed is positively shut off.

All the details of construction may be clearly seen from the sectional cut; 1 is the water fount. The round button 2 shows the height to which the water is filled; 3 is the joint ring on the fount; 4 is the loop into which hook 6 is passed for fastening the top to bottom of lamp; 5 is a clamp and screw which is thrown inward or outward in fastening or unfastening the top from the bottom part; 7 is the joint ring on the top part of the lamp which has cemented to it the round gasket 8; 9 is the stopper which carries the rubber feed valve 10. The stopper 9 has two lugs or projections 11, which are inserted into the slots 12, and is twisted to the left before taking it out or to the right after inserting it. The rubber valve 10 need not be removed at any time except when it is renewed.

The small gasket ring 13 on the stopper prevents the water running into the carbide when the lamp is tipped over; 14 is the metal feed valve which works up and down to close and open the carbide port 15; 16 is the auxiliary stop which registers in port 15 when the lamp is empty.

17 is the carbide holder; 18 is the top wall of the carbide holder which forms a receptacle for the flexible rubber gas holder or bag 19. The bag 19 is permanently secured to the lower side of 18 by means of the threaded nipple 20; 21 is the safety lock and filter combined and is located in the carbide chamber; 22 is the feed stem carrying metal valve 14 and auxiliary stop 16; 23 is the upper spring sleeve and is screwed on the top of feed stem 22; 23*a* is the lower spring sleeve.



CROSS SECTION OF LAMP.

24 is the feed spring which forces the gas out of the holder 19 into the burner. When carbide falls in the water, the gas inflates the holder 19 and expands spring 24, and as the gas passes out of the burner the spring contracts, deflates the holder 19, and forces feed stem 22 downward until an opening is made and carbide falls into the water. The gas so generated reinflates the holder 19 and the operation is repeated automatically until the carbide runs out or until the feed stem is forced upward by screwing in spindle 25.

26 is a bell crank lever pivoted at the side in the bag chamber and in engagement with the top of the bag. The feed stem 22 is screwed into nipple 27 and fastened with a lock nut 28. Nipple 27 is fastened in the top wall of bag by means of nut 29. Under this nut 29, lugs are placed with which the bell crank lever 26 engages.

30 indicates a sleeve which covers the feed spring 24 and is part of safety lock. The upper end of sleeve 30 is secured to the feed stem 22 between spring sleeve 23 and bag nipple 27, so that it has to move with the feed stem and the top wall of holder 19. On the lower end of this safety lock sleeve

is fastened a round metal part 31 with groove 32. In this groove rests a steel ball 33. Around this feed mechanism and safety lock is a casing 34, forming a cage for the ball 33. Immediately above the lower part of this casing 34 is an annular enlarged channel 34*a*. If for any reason the lamp is on its side and in operation, the feed mechanism will continue to move until the opening is made in the carbide port 15, but instead of the carbide falling by reason of the position of the lamp, water will run into port 15 and attack the carbide. Gas will instantly be generated and the holder 19 be inflated to its full capacity, and as the feed mechanism and that part of the safety lock carrying ball 33 are fastened to the top wall of bag 19, part 31, carrying ball 33, will be taken upward to a point parallel with part 34*a*, and the ball 33 will fall from the groove 32, into the annular channel 34*a*. As soon as the gas has burned out to permit the spring to contract the top of the bag, the feed stem and safety lock device will move downward again, but as the ball 33 has fallen into the channel 34*a*, and projects into the path of part 31, the upper part of 31 indicated by 35, will strike against the ball and wedge it between 35 and the edge of channel 34*a*, indicated by 35*a*, and prevent the further opening of the feed port 15. The gas remaining will pass out and burn and the flame go out.

36 is the upper part of casing 34 which carries the felt filter 37, through which the gas has to pass on its way to the holder 19. In this casing are holes 38, which admit the gas. This casing 34 serves: first, to hold the bag 19 in place; second, as a filter; third, as a safety lock, and fourth, as a guide and holder for the feed device; 39 is a flexible tube through which the gas passes from the bag or holder 19 on its way to the burner; 40 is the regulator or reducing valve which serves to give a uniform burning pressure. Below this regulator is another filter 41 in box 42. Box 42 also serves as a support for the shut-off spindle 25. By removing the top perforated cap of the lamp when burning, the operation of the bag 19, bell crank 26, and shut-off screw may be seen.

LAMP SEPARATED FOR FILLING.

The second sketch shows how the lamp is separated for filling. The shade is removed; the top is separated from the bottom part of the lamp and the top part is set upside down on the shade ring, as shown in the figure. The stopper is then removed from the top part, carbide is poured in and the stopper is replaced. The residue is then poured out from the lower fount, and the fount is washed both inside and outside; fresh water is then filled in. The residue is a good fertilizer or disinfectant for toilets.

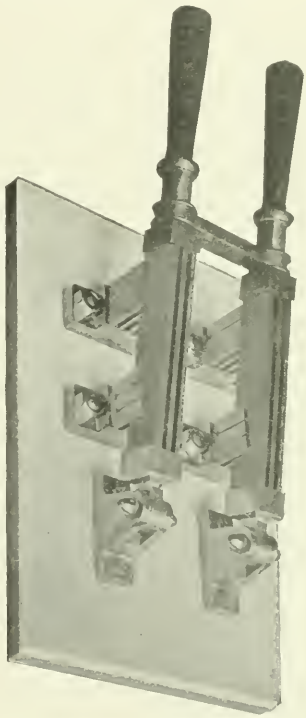
The lamp has been accepted by the consulting engineers of the National Board of Fire Underwriters, and is included in the list of permited acetylene devices issued by them.

## 1,500 AMPÉRE SWITCH.

Electrochemical work is essentially large current work and, therefore, apparatus and appliances for electrochemical plants must be designed just with this point in view.

The adjoining diagram shows the standard Eyanson switch for 1,500 ampères, as made by George T. Eyanson & Co. in Philadelphia, for use in electrochemical plants. All switches, made by this firm for 800 ampères and over, are made up of multiple blades, to insure ample contact surface and ventilation of the parts.

The blades and clips used give a large capacity switch in a comparatively small area. The switch is rated at 1,000 ampères



1,500 AMPERE SWITCH.

per square inch of cross section, and 50 ampères per square inch of contact surface. The blades and dips are of cold rolled copper and all other current carrying parts of cast copper.

## POROUS DIAPHRAGMS.

Porous diaphragms are of very great importance for many electrolytic processes in which the anodic and cathodic portions of the electrolyte are to be kept separate. The quality of the porous diaphragm very often determines the degree to which a certain electrolytic process is successful. In recent years the well-known firm of Villeroy & Boch, in Mettlach, Germany, have made extended researches with a view of finding the best conditions of making a porous diaphragm for use in acid solutions, which shall have at the same time a low electric resistance, a small mechanical permeability, and a long life. From the results of tests made by Dr. Max LeBlanc, and extending over a long time, it appears that the manufacturers have successfully solved this problem. Dr. LeBlanc used these diaphragms in a process of electrically reoxidizing the reduced chromic acid resulting from its use as an oxidizing agent in many industries. Some details given by him in the behavior of these diaphragms are of great interest.

Two different compositions were tried. The older composition was 75 per cent. of $SiO_2$ and 25 per cent. $Al_2O_3$. In the newer type about 2 per cent. of the $Al_2O$ is replaced by alkali. The newer plates are superior to the older ones, in so far as they have a smaller electrical resistance (this means, of course, that the resistance of the electrolyte in the dia-

phragm is matter, as the diaphragm itself acts as an insulator. With a current density of 300 ampère per square centimeter a plate of 5 mm. (or 1.5 inch) thickness showed a drop of potential of 0.4 volt with the older chemical composition, and a drop of only 0.17 volt with the newer composition.

The plates have a different mechanical permeability according to the size of the pores. Diffusion is much smaller through plates with very fine pores than through plates with larger pores. An interesting conclusion reached by Dr. LeBlanc is that it is possible to make a diaphragm which has at the same time a very low electrical resistance and a very small mechanical permeability. In the latest type of diaphragm the pores are so small that they cannot be seen with the bare eye. The diaphragms are claimed to be thoroughly acid-proof and to last practically an infinite time in acid solutions; they are, however, not suited for alkaline solutions.

Messrs. Villeroy & Boch make such porous diaphragms up to the following maximum sizes: rectangular plates 23⅝ inches x 15 inches; square plates 23⅝ inches x 23⅝ inches; cylinders of 27½ inches height and 11⅞ inches diameter; boxes, 29½ inches by 29½ inches by 4 inches.

---

## DIGEST OF U. S. PATENTS PRIOR TO JULY, 1902.

*Compiled by Byrnes & Townsend, Patent Lawyers, National Union Building, Washington, D. C.*

*This digest of electrochemical United States patents prior to July, 1902, will be one by classes, setting out for comparison in each class those devices which have the same object, or those methods which seek the same results. In each class the patents will be arranged chronologically. The digest will be complete in the sense of covering every point which is touched upon in the original specification.*

CAUSTIC ALKALI AND CHLORINE PROCESSES *(Continued).*

508,241. James C. Richardson, London, England, November 17, 1893.

Narrow, rectangular cathode bells, with flared lower ends. Bells open at the upper end, and provided with side outlets for caustic. Cathodes, horizontal grids of copper strips in the flared lower ends of the bells. Anodes, horizontal carbon rods, extending from lead plugs seated in the side wall of cell and serving as terminals.

508,804. Henry S. Blackmore, Mount Vernon, N. Y., November 14, 1893.

Apparatus consists of three rectangular vessels, arranged in a row and connected by siphons. Each siphon is a flat tube, of the width of the vessel, and has an exhaust pipe connected to its bend and a valve at one end. Intermediate vessel contains brine; end vessels, water only. Anode and cathode, perforated, inclined plates in the end vessels, respectively. Perforated salt reservoir depends into middle vessel, and has a steam coil within it. Device for maintaining a constant level in each vessel, and outlets for electrolytic products from end vessels.

510,834. Henry S. Blackmore, Mount Vernon, N. Y., December 12, 1893.

Cell divided by parallel vertical diaphragms into three compartments. Electrolyte fed into one end of middle compartment, any overflow escaping at the other end. End compartments contain water only, and have constant level devices and outlets for electrolytic products. Anode and cathode, serrated, vertical plates in end compartments, respectively. Hydrometer in cathode compartment to show level of caustic. Maintains water level in end compartments slightly above brine level to hinder passage of brine through diaphragms.

510,900. Elisha B. Cutten, New York, N. Y., December 19, 1893.

Iron vessel, serving as cathode, closed at top by an earthenware bell, with water-seamed inlet for brine and exhaust pipe for chlorine. Cathode, a series of vertical carbon bars, supported on an earthenware disc and having carbon pins extending through the disc into a mass of insulation. Insulated wires extend from terminal out through side of vessel. Cathode support rests on a disc of wire gauze, which permits caustic accumulating in bottom of cell, to be drawn off through a central discharge pipe.

511,682. Antoine J. O. Chalandre, Paris, France, December 26, 1893.

Anode compartment, a rectangular box built of non-conducting plates, with rubber packing. A number of inclined porous tubes, arranged in vertical rows, pass through opposite sides of the box. Vertical carbon anodes between the rows of tubes. Cathodes, a series of vertical sheet-iron combs, the teeth of which extend into the tubes. Hood for collecting hydrogen covering higher ends of tubes. Brine circulates between anode compartment and a separate saturating vessel.

512,266. Emile Andreoli, London, England, January 9, 1894.

Rectangular iron vessel, serving as a principal cathode. Supplemental cathode, also a rectangular box, of porous carbon, one or more layers of fine wire gauze, or two layers of wire gauze, with an intermediate space filled with crushed coke or iron filings, arranged within the outer vessel. Anodes of carbon or a basket of platinum gauze. Modification, with slate vessel containing vertical metal-plate cathodes and supplemental porous catnodes. The supplemental cathodes are connected to the principal cathodes by a fine wire, the resistance of which is calculated to shunt the desired current. Made electrolyze sulphates, nitrates, etc.

514,318. Greenwood Division of 489,677.

Cathode, a body of carbon having a cavity or space, the surface of which is electroplated with copper. A copper rod or plate conductor is soldered to the copper deposit.

514,681. Ernest A. Le Sueur, Ottawa, Canada, February 13, 1894.

Stoneware cover of the cell has a cam-ring support for anode. Rotation of the ring adjusts vertical height of anode. The upper surface of cam ribs is also inclined transversely, so that the anode can be tilted to immerse all parts equally in the brine.

518,040. Ernest A. Le Sueur, Ottawa, Canada, April 10, 1894.

Double diaphragm, consisting of spaced sheets of asbestos clamped against opposite faces of a lead frame by non-conducting side frames. Intermediate space filled with brine, maintained at a higher level than in anode and cathode compartments, or with a liquid of greater specific gravity than that in said compartments, thus preventing percolation of anode and cathode solutions into the diaphragm. The entire supply of brine may be fed into the diaphragm, and through it to the cell compartments.

518,785. Ernest A. Le Sueur, Ottawa, Canada, April 24, 1894.

Similar to 518,040. Anode side of diaphragm, a sheet of abestos or porous clay; cathode side, a sheet of parchment, bichromated gelatine or thick cloth, against which is clamped the cathode, of iron netting. May subdivide diaphragm space by a second sheet of asbestos.

520,257. Thomas Craney, Bay City, Mich., May 22, 1894.

Iron containing vessel, connected as cathode. Anode vessel, with curved bottom, of asbestos, cotton or sand, supported by a sheet of cotton cloth on a net and frame-work of iron, in electrical contact with the iron vessel. Anode, a layer of broken gas carbon resting on the asbestos, current being fed to it through a number of perforated clay tubes filled with carbon. Circulation of brine through anode chamber, and of water through cathode chamber. Several cells may be connected by pipes with rubber sections, enabling caustic to flow from cell to cell, or any cell to be cut out for repair. Exhausts chlorine by a fan.

## ELECTROPLATING.

In this issue we print several articles on the practice and theory of electroplating, which we trust may prove interesting to the practical electroplater, as well as to the electrochemical scientist. With the only exception of the battery industry, electroplating is the oldest electrochemical industry; it also is a large industry, there being more than 1,100 electroplating firms in the United States alone, and the products of this industry are in general use. This industry, however, has developed as a separate industry, touched but faintly by the development of other electrochemical industries, and practically unaffected by the progress of electrochemical science. In the electroplating industry, the rule of thumb has been reigning supreme for many years, although recently signs of improvement and healthful progress are plainly evident. But the improvement is due to the introduction of improved apparatus rather than to a better understanding of the principles of electroplating.

The methods and apparatus formerly used by electroplaters were extremely rude. Mr. H. L. Haas, in an article published in this issue, sketches in an amusing manner the method by which in former years an electroplating solution was generally made up by the workingman who had to attend to it. It is a great advance that electroplaters now appreciate the importance of weighing the various materials which they put into the solution. They now understand that to get good results they must exactly know the composition of the solution when they start the operation. Another advance of equal importance is that the electroplater now also recognizes the necessity of carefully producing and maintaining the electrical conditions required to get the desired result. The old-time plater's voltmeter was an old rusty file which they used to put across the two wires, making the connection and getting a spark, since they knew the electric current was flowing, but that was all they knew. In recent years exact measuring instruments are being largely introduced in electroplating establishments, complete switchboards with instruments and rheostats are in the market specially designed for the convenience of the plater. The design of electroplating dynamos was also materially improved. The result is that the electroplater is now in a position of knowing exactly the conditions of his operation by weighing the materials and following exactly the instructions regarding the arrangement of the plant and the regulation of voltage and current, a careful attendant will get good deposits even though he may not know anything about the principles of electrolytic action. This is surely a great practical advance and accounts for the improved results obtained in recent years. But while it would be folly not to appreciate the great practical importance of this progress, yet it is necessary to emphasize that a more important advance must still be made: that is all of us have still much to learn concerning the fundamental principles underlying this subject.

It is certainly a good thing to know exactly the conditions under which a good adhesive deposit is obtained, and to know that by changing the conditions the deposit changes in a certain way. Such knowledge is the result of careful observations and long practical experience. But to apply such knowledge to other different cases, it is necessary to know *why* the deposit is good under certain conditions and poor under others; *i. e.*, it is necessary to understand the general theoretical principles underlying the electrolytic deposition of metals. It is but fair to confess our ignorance of these principles in many respects. Future progress depends upon the co-operation of the practical electroplater and the theoretical scientist; in order to promote such co-operation, we publish the articles on electroplating in this issue, and we hope that they may interest both practical men and scientists in the fascinating problems involved in electroplating. A better understanding of these problems is sure to bring about fruitful results for theory, as well as practice.

At first sight, when viewed from a theoretical point of view, the process of electroplating seems to be one of the simplest cases of electrochemical action, but when studied more accurately it is found to be very complicated. The chemical nature of the electrolyte, the chemical nature of the metal to be deposited, and that of the metal upon which the deposit is to be made, the concentration of the electrolyte the current density and the temperature, all are found to be important factors influencing the properties of the deposit obtained. We know that distinct relations exist between these factors and the properties of the deposit obtained, but we understand these relations only in part. Various interesting observations, mentioned in the articles on the following pages, illustrate this point very clearly.

That the chemical nature of the electrolyte is of the utmost importance, was long known among electroplaters; in fact the patent literature of electroplating is practically a long series of recipes for plating solutions. We know that in many cases certain additions are of great advantage, but we are still more or less in the dark why it is so. For instance, Prof. C. F. Burgess and Mr. Carl Hambuechen, in their article in this issue, mention that a small quantity of carbon bi-sulphide in a silver-plating solution enables a polished coating to be obtained, whereas when omitted the surface would become rough much more quickly. These authors point out that viscosity and surface tension of a solution seem to have some relation to the quality of the deposit; if a substance is added to a metal salt which alters these properties, the quality of the deposit may be influenced. The same authors point out that the quality of the deposit depends upon the degree to which the plating solution wets the surface of the cathode. It is quite evident that to get a good deposit, the solution should thoroughly wet the entire surface; hence, as this property can be imparted by additions of other soluble substances, their addition will improve the deposit. The same authors mention a very peculiar experimental fact: the kind of deposit which was obtained from a zinc sulphate solution prepared by dissolving crystals of zinc sulphate in water was found to be materially different from the deposit obtained under similar conditions of temperature, current density and contents of solution, in which case, however, the solution was prepared by dissolving pure zinc in dilute sulphuric acid until it became of the same neutrality as the solution obtained by dissolving the crystals.

Mr. Woolsey McA. Johnson discusses the same problem—the influence of the chemical nature of the solution—from the point of view of the electrolytic dissociation theory. He calls attention to the fact that double salts are found to give good results in practice, and he advances the view that these good results are due to two different causes: to the increased cathode-potential, and to the fact that the double salt always furnishes the catholyte with a good supply of cations by its continuous decomposition. It will be seen that the influence which the chemical nature of the solution has upon the quality of the deposit, may be considered from very different points of view, and it is quite probable that when this matter will be better understood in future, it will be found that here a great many different influences are playing a role.

The influence of the chemical nature of the metal to be deposited and of the metal upon which the deposit is to be made, is discussed in an interesting article by Dr. Louis Kahlenberg. He points out that the alloying power of the electrolytic deposit with the coated metal underneath is a factor determining not only the strength with which the deposit adheres, but also the length of time the plated article will wear and resist corrosion. There is a tendency of the two metals to dissolve in each other, a tendency of mutual interpenetration of their masses. The stronger the affinity of the metals for each other is, the better the deposit is apt to adhere; a clean, slightly roughened (etched or scratch-brushed) surface facilitates alloying. The practical conclusion reached by Dr. Kahlenberg is to plate those metals or alloys upon each other that possess sufficient affinity to coalesce well, and yet will, at the temperature at which the plated objects are to be kept, diffuse but very slowly into each other.

Prof. Burgess and Mr. Hambuechen discuss the same subject, but think that the alloying phenomenon cannot be held as a universal one. They assume that in some cases no formation of an alloy takes place, but direct cohesion, which is established when solid particles are brought into intimate contact. However that may be, it is certain that what is needed, is intimate contact between the molecular particles of the one metal with those of the other metal—not branches, twigs and outgrowths, but rather roots and a dense undergrowth.

## PATENTS AS LITERATURE.

The United States has issued, to date, upward of 700,000 patents, each of which presumably embodies an original idea, of which the individual patent is a full and adequate expression. These patents are classified according to the several arts, and the vast mass of material so collected constitutes a rich field for study and investigation.

This patent literature, however, does not consist in general of a series of accurate and conservative monographs; it is rather, for the most part, in the form of more or less fragmentary notes written by the inventor, or, at least, from the inventor's viewpoint, and expressing not so much the accomplishment of a result as the formulation of a hope.

Of course, there are exceptions—descriptions so clear and convincing that the patent specification is what the law intended that it should be, a clear expression and definition of the patentee's contribution to progress. Too often, however, the description is a recital of imaginary defects of the devices of the prior art and illusory advantages of the new construction. In such cases an effort to attain any clear idea of the practice of the day or of the development of a given principle, through a study of the patents alone, will be futile.

This is unfortunate, but in large part it is irremediable. The average inventor is often characterized as visionary, which is true in part only. More accurately, his dominant characteristic is hopefulness, and no law exacting accuracy will ever prevent him from painting his thought with the bright colors which, to him, are real. To read patents with profit, one must understand this and sympathize with it; one must see with the inventor's eyes in order to understand his thought. Then whatever of value or suggestiveness the idea may contain will become clear.

## ON ENTROPY.

A very animated and amusing war on entropy is raging at present in our British electrical contemporaries. In a note in his recent presidential address to the (British) Institution of Electrical Engineers, Mr. James Swinburne claimed that nearly all text-books are wrong in defining entropy. This remark elicited a sharp answer by Past President Prof. John Perry, which was followed by others, and the war is still going on merrily. If it was simply a quarrel on technical terms, a new case of the tower of Babel, there would be no use in saying much about it; we could simply mention that Mr. Swinburne claims to base his views directly upon Clausius, who coined the term and established the second principle of thermodynamics; and that, according to Professor Perry, it is a matter perfectly well known that Clausius used a term in one sense and all modern men use the same term in another sense (the term "all modern men" being again open to discussion); and that Lord Kelvin says entropy is Clausius' word, and persons concerned in it will find its definition in Clausius' own writings.

However, it is not simply a quarrel about words. If we understand Mr. Swinburne correctly, he wants to protest against the predominant place which is given to reversible processes in the discussion of the second principle of thermodynamics in ordinary engineering text-books. He wants to emphasize that reversible processes are only an ideal case, never fulfilled in practice, and that, in fact, the cardinal point of the second principle of thermodynamics is that in nature we always have irreversible processes, in which the entropy always increases. And in this respect Mr. Swinburne is right, without doubt. The well known integral representing the heat supplied from an outside reservoir to the system under consideration, divided by the absolute temperature at which this heat exchange takes place at any moment, serves only as a method of determining the value of the entropy, and it is here an essential supposition that the process by which the system is brought from one condition to another is absolutely reversible. Thus the reversible processes serve only for determining the value of the entropy, but in nature we have only irreversible processes.

The difficulty in the whole matter seems to arise from the fact that the value of entropy is found by determining the value of the integral mentioned above for a reversible process. Being thus mathematically defined, its physical meaning is obscure. We here arrive at a limit of our knowledge. We can give the value of entropy, independently of that integral, only for gases and dilute solutions, but in all other cases we must go back to that integral. Nevertheless, we should take pains to connect a physical meaning with the word entropy. If we do this many misunderstandings will disappear, and especially the fundamental difference which exists between the principle of the conservation of energy and the principle of the increase of entropy will become evident; that is, the difference between the first and second principles of thermodynamics. It is still too often thought that the second principle of thermodynamics is only an appendix to the principle of the conservation of energy, while, in fact, it states something with which the energy principle is not at all concerned.

If an isolated system is given which passes from one condition into another, the first principle of thermodynamics states that the energy of the system in one condition is exactly the same as in the other. Viewed from the principle of the conservation of energy, there is no preference for either condition; both are equivalent, and in both the system has the same energy. But we know that a change will always take place in a certain direction, and not in the opposite direction. The energy principle does not indicate in any way what this direction is, but the second principle of thermodynamics does. This is indeed the fundamental point of this principle. We can accordingly give a popular definition of entropy, which we believe is due to Planck. It is that the entropy of a system is the function representing the preference which nature gives to one condition of the system above another condition. Entropy will therefore always increase. To mention one instance, if we have two solutions of the same electrolyte, but of different concentrations, this system of the two solutions has a certain entropy. When the two solutions diffuse, the entropy increases, because this is an irreversible process. Hence the process will always take place in such a direction that the dilute solution becomes more concentrated, and the concentrated solution more dilute. This enables us, for instance, to always predict the direction of the e. m. f. in a concentration cell, and it is absolutely wrong to assume that it is of any influence whether the heat of dilution is positive or negative. It is true Berthelot believed that the direction of a chemical process is determined by the amount of heat which the action can evolve; the reason why hydrogen and oxygen combine and form water, and why not the reverse takes place, is, according to Berthelot, that the former process evolves heat. True, this view has been predominant in thermochemistry for many years. But we know now that Berthelot's principle is wrong as a general principle, and in its place we have the second principle of thermodynamics: a chemical process takes place in such a direction that the entropy increases. We hope to return to this point in connection with some special electrochemical subjects in future issues.

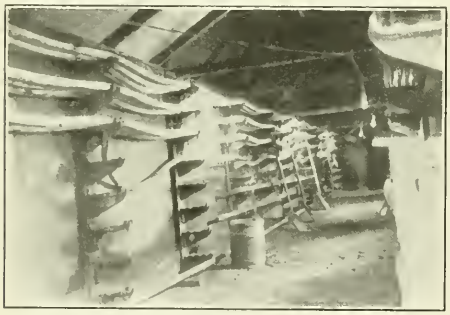
## NIAGARA POWER PLANT COMPLETELY SHUT DOWN BY FIRE.

By Frank C. Perkins.

The thunder shower of Thursday, January 29th, damaged the 75,000 horse-power Niagara Falls power plant to such an extent that it was necessary to stop every one of the fifteen 5,000 horse-power alternating-current generators. All of the current from the 50,000 horse-power plant in power house No. 1 passes through the cable bridge, carrying the current from the power house to the step-up static transformers in the transformer house across the canal. The temporary connections of the new power house No. 2 were also of such a nature that the fire which occurred in the cable bridge and transformer house made it impossible to utilize these machines.

It is believed that a stroke of lightning formed a serious short circuit in a 2,200-volt local circuit in the cable bridge, and the roof of the bridge, which was of wood, took fire, as well as that of the transformer house, resulting in the destruction of every high-tension lead-covered cable between the power house and the transformer, shutting down the entire plant.

In extinguishing the fire large quantities of water were poured into the transformer house, badly damaging the air-cooled transformers, which were located near the entrance to the cable bridge. It is thought that little damage was done to



CABLE BRIDGE ON THE MORNING AFTER THE FIRE.

the oil-cooled transformers by the fire, and the air-cooled transformers may be serviceable as soon as thoroughly dried out.

The accident happened about midnight, and the quick work of Superintendent Philip P. Barton and his men resulted in the replacing of 36 of the cables before morning and the replacing of a temporary roof on both bridge and transformer house, and four 5,000 horse-power machines were in operation.

Of the total 75,000 horse-power generated in the two power houses, about one-third is transmitted over the 22,000-volt lines to Buffalo for operating the street railways and lights of the city, as well as furnishing power to many of the newspaper establishments and various factories. The storage-battery plants of the International Railway Co. and the Buffalo General Electric Co. were of service for several hours, and the large reserve steam plant of the railway company was soon placed in operation and the car lines were never all shut down.

The arc and incandescent-lighting service of Buffalo and Tonawanda was not so fortunate, and both cities were without light until Thursday evening.

The power plant of the Niagara Falls Hydraulic and Mfg. Co., which obtains its power from a surface canal through the city of Niagara Falls, was able to render great assistance during the trouble, and the lights of that city were kept in operation, as well as the street railway service.

It is stated that the damages will probably exceed $50,000, and undoubtedly as much again if the losses of the tenants and other power users is considered. The construction of the bridge and transformer house is entirely of iron and stone, except the roofing, which is of wood. And while the fire itself caused little or no damage to the transformer plant, the water, of course, put the transformers of the air-cooled type entirely out of service for the time being. Had tile or other fire-proof roofing been used, undoubtedly the damage would have been much less, and might have saved the plant from being entirely closed down. A second conductor bridge, with duplicate cables, would unquestionably have rendered the accident less serious, as "all of the eggs would not have been in one basket," and the current might have been sent to the transformer house through the second set of conductors.

It may also be considered doubtful whether it is wise to place all of the transformers of a 50,000 horse-power plant in a single building, as the burning out of one or more may affect a number of others. This disastrous fire at the Niagara Falls plant shows how much care is necessary in the protection against lightning and the desirability of using fire-proof materials in every portion of a modern electric power plant.

The duplicating of transmission lines is now extensively practiced, and is undoubtedly advisable. And there is little question but that the engineers of the five new plants being constructed on both sides of Niagara River, above and below the falls, will carefully consider the causes of this serious shut-down in all its phases, and endeavor to make such provisions that a similar accident will be impossible.

The engineers of the Niagara Falls power plant are to be congratulated on the rapidity with which they were able to place their power lines in service again after so serious an accident. This is, however, characteristic of electrical engineers in both lighting and power plants. They usually are equal to almost every emergency, no matter how serious it may be. The accompanying illustration shows the interior of the cable bridge the morning after the fire, with new cables in place and roofing completed.

## PROPOSED (BRITISH) SOCIETY OF ELECTRO-CHEMISTS AND METALLURGISTS.

At a meeting of the Provisional Committee of the proposed (British) Society of Electrochemists (see Electrochemical Industry, Vol. I, page 4, Sept., 1902), held on January 6th, Mr. James Swinburne in the chair, it was resolved, in consideration of the support and encouragement received in response to circulars recently issued, to hold, on February 4th, a general meeting of the supporters of the movement and formally inaugurate the work of the Society and elect a president and council.

It has been suggested that there should be two classes of members—members and associated members—the subscription fees being two guineas and one guinea respectively (*i. e.*, about $10 and $5).

The honorable secretary of the Provisional Committee is F. S. Spiers, 82 Victoria street, London.

The following gentlemen have consented to be nominated as members of council of the proposed society: President, J. W. Swan, F.R.S.; vice-presidents, Prof. A. Crum-Brown, M.D., D.Sc., F.R.S., Sir Oliver J. Lodge, D.Sc., F.R.S., Dr. Ludwig Mond, Ph.D., F.R.S., Lord Rayleigh, D.C.L., F.R.S., Mr. Alexander Siemens and Mr. J. Swinburne; council, Messrs. George Beilby, Bertram Blount, W. R. Cooper, M.A., B.Sc., Sherard Cowper-Coles, A. G. Charlton, F. G. Donnan, M.A., Ph.D., Prof. A. K. Huntington, F. Mollwo Perkin, Ph.D., W. S. Squire, Ph.D., and O. J. Steinhart, Ph.D.

Statistics of Electroplaters. Census Bulletin No. 150, issued September 15, 1902, gives the number of electroplating firms in the United States in 1880 as 221, and in 1900 as 422, the value of their products being given as $1,975,700 and $3,007,455 respectively. The number of "galvanizing" firms in 1900 is given as 28, and the value of their products as $2,470,703. It seems that these figures are too low, for, according to reliable private information, there are more than 1,000 electroplating firms in the United States.

## THE ALLOYING OF METALS AS A FACTOR IN ELECTROPLATING.

BY PROF. LOUIS KAHLENBERG, PH.D.

At the meeting of the American Electrochemical Society, at Niagara Falls, Professor Haber demonstrated experimentally that when an aqueous solution of a salt of sodium or potassium is electrolyzed, using a cathode of tin or lead, hydrogen is formed, and a dark cloud, consisting of the finely-divided heavy metal, envelops the cathode. With a lesser current density, the cloud does not form, the surface of the heavy metal being simply roughened. It was pointed out by Professor Haber that here the alkali metal actually is deposited on the cathode, forming an alloy with the latter, which is then decomposed by water, yielding hydrogen secondarily and the finely-divided metal. This experiment is of great value in settling the mooted question of whether the hydrogen liberated at the cathode during the process of electrolysis of an aqueous solution of a salt of an alkali metal is of primary or secondary origin. While, as Professor Haber stated in the conclusion of his paper, the experiment is perhaps of more theoretical than practical interest, nevertheless it is simply a striking illustration of a general fundamental principle that underlies all electrolytic deposition of metals.

When one metal is deposited electrolytically upon another, the process of alloying always goes on to a greater or less extent, which is determined primarily by the nature of the metals, and secondarily by the conditions of experiment. Among the latter are of special importance the original condition of the surface of the cathode, nature and concentration of the electrolyte, temperature, potential and current density. These all have been well recognized and thoroughly discussed in text-books as important factors in securing desirable, dense, well-adhering deposits that will admit of being polished and burnished. The important fact that the alloying power of the electrolytic deposit with the coated metal underneath is a factor determining not only the strength with which the deposit adheres, but also the length of time the plated article will wear and resist corrosion, has not been sufficiently recognized.

The alloying power of two metals consists of a specific attraction of the metals for each other, a tendency to dissolve in each other, or, as it is put by others, a tendency that the metals have to bring about a mutual interpenetration of their masses. This force is no doubt chemical in character, slight though the affinity may be in some cases. The alloys of mercury, the amalgams, especially those of the alkali metals, have become of considerable importance in the electrolytic preparation of caustic alkalies and of alkali metals. Here the alloying of the alkali metal with the mercury constituting the cathode is well recognized. But when gold is plated on lead, for example, an alloy of gold and lead is just as truly formed at the point of contact between the two metals. A thin plating of gold on lead will gradually soak into the lead entirely as the alloying process continues. This goes on at room temperatures. The experiments that Roberts Austen made in 1900 ("Proceedings of the Royal Society," London 67, 101-5) demonstrating how gold diffuses into lead at ordinary temperatures are of special interest in this connection. A thin plating of gold on zinc is absorbed in a few days. The "tarnish" becomes visible very soon. After the deposit has been absorbed, the gold may be exposed again by carefully etching away the zinc from the surface by use of a dilute acid. The experiment of Gore, illustrating how copper plated on platinum penetrates into the latter, is well known to electroplaters.

This affinity between metals asserts itself the moment one metal is deposited on the other. The stronger the affinity of the metals for each other is, the better the deposit is apt to adhere. On the other hand, the plating is also more apt to be absorbed by the base metal underneath the greater the tendency of the metals to alloy is. A higher temperature generally aids this alloying process, and so it is that frequently much better adhering deposits are obtained by working at temperatures above the ordinary. A clean, slightly roughened (etched or scratch-brushed) surface of the cathode clearly facilitates the alloying of the deposit with the metal of the cathode, for thus a more intimate contact is secured. When two metals are to be alloyed under ordinary conditions, the affinity between them must overcome their cohesions. This frequently requires a high temperature. In the process of plating the affinity between the metals clearly does not initially have to overcome the cohesion of the deposited metal, since the latter is gradually built up, starting with an exceedingly thin film. Thus it is that alloys of metals may readily be formed at room temperatures by electrolysis, whereas under ordinary conditions the alloys would not form at all, or would form but very slowly. The fact that platinum will not amalgamate with mercury under ordinary conditions, and that platinum amalgam may readily be prepared electrolytically, is a good illustration of this.

In the case of any plated article, the deposit and the metal underneath continue to act upon each other, or mutually diffuse into each other. This action is great between zinc and gold or lead and gold, as has been stated above. Between copper and gold and brass and gold it is less noticeable. And yet who has worked with brass, gold or platinum-plated weights and has not noticed that the plating is, after all, but a relatively poor protection against corrosion? Especially as the weights grow older they are all the more easily corroded by moisture and traces of salts in the atmosphere of the laboratory. If the plating is heavy, this corrosion will, of course, not take place so early as when the coating is thin, which is so frequently the case.

The mechanical character of the alloy formed by the deposited and the base metal is also of practical consequence. If the alloy has a strong tendency to become crystalline, or is brittle, or has a considerably different co-efficient of expansion from that of the pure metals, the deposit is more apt to chip off than if the alloy is pliable and does not exhibit tendency to crystallize.

Nickel may be successfully plated on copper and its alloys—brass, bronze, etc.—for with these nickel alloys readily. On the other hand, when an object of lead is to be nickeled, it is first copper plated, and then the nickel is deposited on the copper. In this operation use is made of the fact that copper alloys readily with nickel, and copper alloys better with lead than does nickel; and so copper serves here as a cement, as it were. Many other similar illustrations from practice might be cited.

In general, then, metals that will alloy readily with each other may, other things being equal, successfully be plated on each other. Whether the plating will be absorbed faster or slower will depend on the character of the metals and the temperature at which the object is kept, as noted above. If the deposit consists of a metal of the same color as the base metal underneath, as, for instance, gold over brass or copper, the effect of this diffusion of the metals into each other will not be so apparent as when the metals are of different hue—gold on lead or zinc. And yet metals of very different color may at times be plated on each other, and the effect of this diffusion remains unnoticed because the alloy formed has the color of the plating even up to very high concentrations of the alloy. Nickel on copper is a good illustration of this.

While it thus appears that a strong alloying power is desirable between base metal and electrolytic deposit, as it tends to secure good adhesion of the latter, it is also evident that this tendency to form an alloy frequently militates against the very purpose for which the electrolytic deposition was made, namely, to secure a better appearance or to protect from corrosion. It is evident that in the long run all plated objects must slowly deteriorate, even when not in use and when carefully protected from the atmosphere by a lacquer of some kind. The electroplater must study the subject carefully so as to plate those metals or alloys upon each other that possess suffi-

cient affinity to coalesce well and yet will, at the temperatures at which the plated objects are to be kept, diffuse but very slowly into each other. He will also choose the color of the metals or alloys so that the final alloy formed may have the same, or nearly the same, shade as the electrolytic deposit and will itself be corroded less readily than the base metal alone.

The connection between soldering and electroplating of metals is evident from what has been stated. So, for instance, the difficulty of plating on aluminium and of soldering the metal go together, though, of course, the fact that this metal is readily oxidized, and that the oxide coating interferes with both processes, must not be lost sight of. It is not so easy to solder iron with the usual half-and-half solder, as it is to solder zinc, though the latter metal is much more readily oxidized than iron. The explanation is clear: iron does not alloy as readily with the tin and lead solder as does zinc.

A careful, systematic study of the electrolytic deposition of the metals from the standpoint of the alloys formed will no doubt yield results of further practical value.

Laboratory of Physical Chemistry,
University of Wisconsin, Madison.

## THE SMELTING OF IRON ORES AND THE PRODUCTION OF STEEL IN THE ELECTRIC FURNACE.

By Marcus Ruthenburg.

The application of electricity to the smelting or iron ores or the production of steel, either from the ore or previously smelted pig iron, is not a matter of merely recent endeavor.

Attempts, more or less successful, have been made for a number of years in this direction, more especially in Europe, where proper fuel was deficient or too costly, and where water-power, cheap in comparison with available fuel, could be readily obtained.

Therefore, it has been broadly stated, that it was only in such an environment that the electrical production of pig iron or steel could be carried out, upon a commercially successful basis.

In this country, near Niagara Falls, there has been for several years, in intermittent operation, a plant for the production of special alloys of iron. The operator of this plant, in a lengthy and learned article, in a recent issue of *The Iron Age*, went into the subject of the smelting of iron ores electrically, exhaustively, and proved theoretically and practically, that it required the continuous expenditure of 200 horse-power, to produce one ton of metallic iron in twenty-four hours. In other words, that it required 4,800 horse-power hours. Stassano, in Italy, claims to smelt a ton of finished product with 3,000 horse-power hours. De Laval, in Sweden, calls for 3,500 horse-power hours, and Rossi at Niagara Falls uses 4,800 horse-power hours. I have thus set forth what the more prominent experimenters and operators have claimed for themselves, not with the object of invidious comparison, but to state clearly what you might call the condition of the art.

In France, three separate and distinct plants have more recently been put in operation with power consumption differing not materially from the above.

How their conclusions as to power consumption have been arrived at, is a detail that none of them have enlightened the public upon. More than likely it has been done by taking periodic readings of voltmeters and ampèremeters, which is far from conclusive, as both volts and ampères are given to fluctuations, both sudden and excessive, leaving to the one taking the readings the exercise of his judgment as to what the reading should be.

Using a recording watt meter is the only way that this power consumption can properly be arrived at. It takes cognizance of pressure, current and time, and all the attendant has to do is to read his meter and weigh his product.

Before describing some of my own work in electrical smelting of iron ores, there is another point that I want to call attention to, and that is the cost of electric current per kilowatt hour, or per horse-power hour. So many people are in the habit of pointing to Niagara Falls as the place of all places, to secure an unlimited supply of electric current, at economical, if not cheap prices. Cheapness must always be comparative, that is, something is cheap, when of equal quality it can be produced for less in one place than another.

I have long asserted that in their anxiety to get something for nothing, engineers have rushed to remote and out-of-the-way places to capture a promising water-power, and ignored what could be accomplished with large steam actuated electric units.

Let any of these gentlemen figure up what a kilowatt hour can be produced for, based upon the coal consumption and cost of operation and maintenance of a 1,000 or still better a 5,000 kilowatt unit. He will then find that a fair quality of coal, with the facilities that any large plant would of necessity be provided with, will put the prices now asked by prominent water-powers, very much in the shade.

My own work in the electrical smelting of iron ores has been of a practical nature, and my efforts have been bent to the accomplishment of the work upon a basis that would not only permit of universal use of the method, as an offset to blast furnace and open hearth steel practice, but would also produce superior metal at a materially less cost. In a nutshell, this statement resolves itself into a question of how much power I use to accomplish my work, and in a nutshell

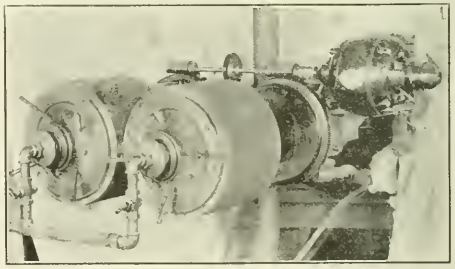


FIG. 1.—VIEW SHOWING BRIDGE OF ORE BETWEEN ROLLS.

the answer is, less than 500 kilowatt hours to produce a ton of product.

Some very learned gentlemen have undertaken to prove that "this was not possible"—that "it was an unheard of efficiency," and that "even if it were so, the vast stores of high-grade ores at our command and the efficiency of the blast furnace made the man who offered to replace the blast furnace simply a happy optimist." To these gentlemen let me simply say, show me the supply of high-grade ore, open to the independent operator, and I will undertake to "make him rich beyond his dreams of avarice." As to the economy of the blast furnace the same learned gentlemen will agree with me, that of the ton of coke, which even good practice requires to make a ton of pig iron, but a little over 300 pounds are required for the chemistry of the furnace, *i. e.*, reducing the iron. The balance is required to melt not only the reduced iron, but the medley of earths and the lime which go to form the cinder. An important portion is also consumed in the production of waste combustible gas, some of the value of which is recoverable under boilers and in the stoves for preheating the blast. As against this, what is a fair statement of the operation of an electric furnace producing a ton of metal with a consumption of 500 kilowatt hours.

The 500 kilowatt hours will require the combustion of 1,000 pounds of soft coal (not coke). The reduction of the ore will

require 300 pounds of carbon = 700 pounds of fuel, saved at the outset. At the present abnormal prices of coke and coal any comparison of price would not be of any particular moment, though ordinarily coke costs about twice as much as coal. Suffice it to say, you melt your ore with cheap coal as against costly coke, and further, you do it with the saving of 33 per cent. of the fuel's weight. Of course, the question that interests any one conversant with these matters is, how do you effect a saving of 80 per cent to 90 per cent. in power, over what others have done in the same field. Apparently I do—but I don't. The truth is—we don't do the same thing.

It has been and is (with the exception of my method) the practice to melt the ore and maintain it molten, the molten mass being a path of low resistance for the passage of the current, in which reduction takes place by the hot carbon of the electrodes and the gases of carbon given off. To maintain this mass molten requires the large expenditure of energy. Instead of this my work consists in holding the ore (but a small portion at any one instant) by a powerful magnet. Only the portion held by the magnet is melted, the ore supply from above resting upon the magnetic bridge and being thereby restrained from slipping through. The poles of the magnetic circuit are also the poles of the melting circuit. Electrodes, there are none, the resistance being the ore itself, which as fast as fused is carried out of the zone of fusion and dropped, its place being taken by ore from above.

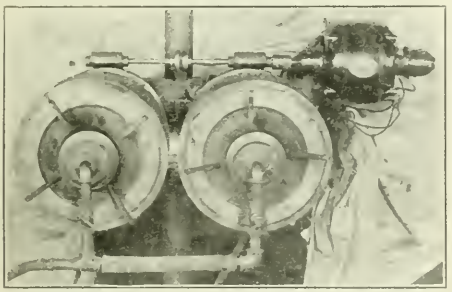

FIG. 2.—FRONT VIEW, SHOWING BRIDGE HEATED, 700 AMP., 50 VOLTS.

Preparatory to the electric furnace, the ore should be cleaned up to the highest possible point, so as to avoid the treatment of useless earthy and cinder-forming matters. Magnetic ores may be quite lean and yet pay to crush and clean. In some cases the crushing must be quite fine to produce economic results. This iron dust cannot be used in a blast furnace, but is just what the electric furnace wants, the finer the ore the more intimate the mixture of the charge may be and the more thorough the reduction.

The ore is mixed to produce the desired chemical analysis of the finished material and the required reducing material is incorporated. At the high temperature of the electric furnace the charge is fritted into a homogeneous mass, minus a large part of its oxygen, and is discharged from the furnace very hot and kept hot so that the cementation may finish the elimination of the contained oxygen. The material is then ready for melting in an open hearth furnace and is steel.

The accompanying pictures are photographs of a furnace now in operation.

A little study will show the horizontal horseshoe magnet, divided and insulated (electrically) at the bend of the magnet, the supporting post forming the pin of the hinge joint. The magnetic poles are within the bronze revolving rolls against whose surfaces the melting is done. They are water-cooled. The rolls are driven at four revolutions a minute by the small motor and the worm gears, making roughly, 16 feet of peripheral speed a minute.

## THE ABUSE OF ELECTROPLATING.

By H. L. HAAS, PH.B.

Electrometallurgy has, until very recently, been wholly in the hands of unscientific men, workmen who have never given it the proper attention as a science.

Formerly very little attention was paid to the composition of a plating solution, nor what chemical changes took place in it during electrolysis. When a solution did not deposit its metal properly, the plater thought it needed a handful of this or a spoonful of that, and threw it in, not knowing whether it was soluble in the solution or not or what change was produced. And when that did not work, he thought perhaps it needed another handful or spoonful of something else, irrespective of any exact quantity or what the chemical change would be by the addition of it. And when it still did not work he was at a loss what to do further, so did the only thing possible—threw it away and started to make a new one (because he was a plater and not a scientist). But the new solution was no better than the first. And why? Because he had made it with a handful of this and a spoonful of that and an unknown quantity of something else that he had forgotten the name of (because he was a workman and not a scientist).

If he bought certain chemicals, the nature of which he did not know, or what percentage of purity, he was again in trouble when his solution did not work properly, because he had made it in a careless manner with only a workman's knowledge.

He had electric current, to use his expression, yet the solution did not deposit. He knew only that he had a current, because when he connected the positive and negative wires he obtained a spark.

The platers' voltmeter was formerly an old, rusty file, which they used to put across the two wires, making the connection and obtaining a spark. Then they knew they had electric current, but they did not know or care how much they had, because they had never measured it.

Electroplaters should know the following in order to be thoroughly conversant with their work:

First. Exactly what the depositing solution is made of.

Second. What takes place in the solution during the action of the electric current.

Third. What chemicals they are using, their properties and purity.

Fourth. The solubility of the anodes.

Fifth. How much electric current is necessary to deposit the metal properly; how many volts and ampères are employed.

Sixth. How much resistance the solution and anodes offer to this electric current.

Seventh. The distance between the cathodes and anodes, and whether it varies.

Eighth. The amount of metal that is dissolved in a given time by the action of the electric current on the anodes.

Ninth. The amount of metal that is being deposited on the cathodes.

In this manner the plater is in a position to determine at all times what is going on in his solution, and if anything is wrong can obviate the difficulty, because he knows instantly the remedy for it.

For example, as in the case of silver and gold, the best plating solution is composed of cyanide of silver or gold. Cyanogen is evolved at the anode and silver or gold, as the case may be, is deposited upon the cathode. Chemicals used for making these solutions are cyanide of potassium and chloride or nitrate of silver or gold, or cyanide of silver or gold.

It is a known fact that, when subjected to the electric current, these two metals are dissolved very rapidly at the anode. The consequence is, when plating with them, very small anodes are all that are requisite to keep the metallic strength of the solution up to the proper standard.

In the case of copper and brass, which do not dissolve in

[illegible] platinum, is readily as the two former metals when subjected to the action of the electric current, a larger surface of these two metals should be employed as anodes than in the case of silver and gold.

With nickel, it is a known fact that this metal is only with great difficulty soluble in sulphate of ammonia (which is the regular solution used for nickel plating) by means of the action of the electric current, and as a consequence the largest possible surface of nickel anodes should be employed.

It has been practically demonstrated that the maximum plating surface of nickel anodes that can be placed in a tank of a given size, even when suspended on both sides of the cathodes, were not sufficiently dissolved by the action of the electric current to give the same amount of metal to the solution that was deposited upon the cathode, consequently the solution would in time become too weak in metal; therefore a larger surface of nickel must be placed in the bath, and the only manner in which this can be accomplished is by adding metal in some form to the solution. Formerly this was done by means of the addition of fresh nickel salts dissolved in the solution, which was both detrimental and expensive. Then the corrugated nickel anodes were invented, and it was practically determined that if one-third more surface of nickel was subjected to the action of the electric current in a nickel solution, the same amount of nickel would be dissolved into the solution as was deposited on the work, and as a consequence the solution remained almost constant in metallic nickel, thus obviating the addition of metal in any other form.

I advocate that all plating solutions should be made as simple as possible. By this means the plater, knowing at all times what is taking place in his solution, can readily remedy any error. But if the solution is complicated, and there are various chemicals that really have no special advantage, should the solution go wrong the plater is at a loss to know where the trouble lies, and therefore is apt to ruin his solution in trying to doctor it.

I have been endeavoring for many years to bring this up to a scientific standard, and with many gratifying results.

At the present time platers are giving more attention to the composition of their solutions. They weigh their materials; they endeavor to acquaint themselves with the action that the electric current produces on a solution; they pay more attention to the electrical contact, their different connections, the advantages of keeping them clean and free from all corrosion. They are using voltmeters and ammeters for measuring their electricity, switchboards for reducing their current to the proper and best point for the proper deposition of the metal, and I am pleased to say that the results which are now obtained in plating of the various metals are far better in every way than formerly. And I feel confident it will only be a few years when it will have reached the high standard of other sciences.

## THE PHYSICAL CHARACTER OF METAL DEPOSITS.

By Prof. C. F. Burgess and Carl Hambuechen.

IN the passage from a liquid to a solid condition a substance usually assumes a crystalline structure, the form of which is influenced by various factors, such as chemical composition, temperature, density, etc. Electrodeposition is the passage of metals from the state in which they exist in a solution to a solid state through the aid of the electric current. In passing an electric current through an aqueous solution of a metal salt, the metal in the solution is caused to separate out, changing its physical condition and developing properties of cohesion between metal particles thereby deposited. The amount of cohesion between metal particles after separation from the solution varies through a wide range, depending upon the various conditions of operation. Under certain circumstances, the metal may assume regular geometrical forms or crystals, and, in fact, metals are almost invariably deposited in such forms. Although to the eye a deposit may appear amorphous, under the microscope it may be shown to consist of a great number of minute crystals in juxtaposition.

The appearance and character of a growth of metal is determined to some extent by the size and shape of the crystals and the manner in which they build up. They may assume innumerable forms, all the way from spongy and almost gelatinous masses to coarse crystalline and dense structures. With suitable conditions of current, solution and

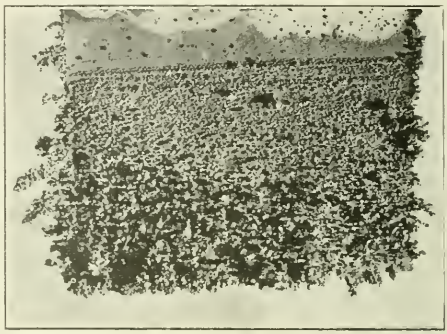

FIG. 1.—ZINC DEPOSIT.

metal, growths may be produced which will assume almost any of the forms of plant vegetation, to which they may perhaps be best compared. A photograph of a copper deposit might, with suitable background, be mistaken for a tree in the winter time, with trunk, branches and twigs. Various kinds of trees may also be produced in miniature with such exactness as to show the formation of buds and leaves upon them. The grasses, ferns and mosses may be produced in form in a similar manner. So much do these forms resemble plant growth that the term metallic vegetation has been applied to depositions of metals which are produced by electrolytic means.

A study of the conditions under which various forms of

FIG. 2.—COPPER DEPOSIT.

metallic vegetation can be cultivated is very interesting and a promising field for research, inasmuch as the exact conditions for the growth of various kinds of formation are very little understood. From the practical standpoint, the study of these growths is important, not so much as showing how they may be cultivated, but rather how they may be suppressed. It is not branches, twigs and outgrowths that the electroplater or electrorefiner wishes to obtain, but rather roots and a dense undergrowth. Knowledge as to how the conditions may be regulated so that this may be effected governs the success of many technical processes. The factors determining the forms of deposits and those which the metal depositor has in his

power to regulate are the following: Chemical composition, concentration and temperature of the solution, the current density and circulation.

The accompanying illustrations are taken from photographs of metal deposits, and illustrate a few of the typical formations which are frequently obtained. Fig. 1 shows the shrub or fern-like growths of zinc. Fig. 2, the larger tree crystallization of copper. Fig. 3, a reproduction of the growth around the edge of the cathode receiving an iron deposition. Fig. 4, the appearance of crystalline lead as deposited from a lead acetate solution.

The most important factor in regulating the quality of the deposit is the composition of the solution. As is well known,

FIG. [illegible] IRON DEPOSIT ON EDGE OF CATHODE.

the deposit obtained from a nitrate, sulphate, chloride or other solution of a particular metal is to a large extent characteristic of the particular solution used. The presence of certain substances added to a metal solution will also influence the kind of deposit, sometimes for the better and often for the worse. Aluminium sulphate added to a zinc sulphate solution affords a marked improvement in the quality of zinc deposit, although the aluminium sulphate itself undergoes no chemical change. A small quantity of carbon bisulphide in a silver plating solution enables a polished coating to be obtained, whereas when omitted the surface would become rough much more quickly. A similar effect may be produced by introducing a very small amount of gelatine into a nickel-plating solution although if the amount exceeds a certain very small quantity the coating will be rendered worthless. The importance will, therefore, be seen of not only paying attention to the chemical composition of the solution, but to its purity as well.

At the present time there seem to be few guiding principles showing what substances may be introduced to a metal solution to advantage, and what substances should be avoided. The physical character of the deposit, being so greatly influenced by the quality of the solution, seems to indicate that the solution itself has some physical structure, such as a peculiar arrangement of molecules or other physical characteristics, which determine what the character of the deposit obtained from it will be. If the solution has some cellular structure which would correspond to the crystalline structure of solid we would have some explanation of the marked influence on the quality of deposit which the introduction of some foreign substance to the solution will exert, inasmuch as the structure of the solution itself would be influenced thereby. There seems to be some grounds for the belief that the viscosity and surface tension of a solution has some relation to the quality of the deposit, and that if we add a substance to a metal salt which will alter the above properties the quality of the deposit may be thereby influenced.

A fact that is worthy of note, and which may explain the differences in the results obtained by different experimenters, and the difficulties which have frequently been encountered in reproducing effects which have previously been obtained, was brought out in some work being carried on by Mr. C. L. Zimmerman in the electrochemical laboratory on the deposition of zinc. He found that the kind of deposit which was obtained from a zinc sulphate solution prepared by dissolving crystals of zinc sulphate in water was materially different from the deposit obtained under similar conditions of temperature, current density and content of solution, in which case, however, the solution was prepared by dissolving pure zinc in dilute sulphuric acid until it became of the same neutrality as the solution obtained by dissolving the crystals. A similar characteristic has been noted in the deposition of iron from sulphate solutions made by dissolving iron sulphate in one case, and iron in sulphuric acid in another. It has further been found that the boiling of a solution and the subsequent cooling to room temperature may also materially change the character of the deposit.

The effects of concentration of solution, temperature and current density have been more carefully investigated than has the effect of the chemical and physical nature of the solution, and it is not the purpose to deal here with those factors.

In the deposition of metals for ornamental and protective purposes it is not only important that the metal deposited shall be firm and uniform throughout the entire surface, and that the particles of metal shall have considerable coherence among

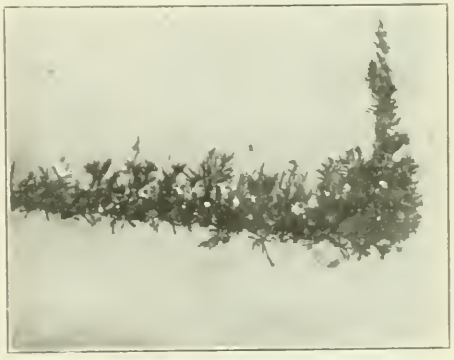

FIG. [illegible] [illegible] OF ZINC.

themselves but what is equally important, there should be a strong cohesion between the metal particles deposited and the metal surfaces upon which they are deposited. This, as is well known, depends very largely upon the surface cleanliness which influences the intensity with which metals deposited upon the same will adhere. It also depends to a certain extent upon the metal receiving the deposit and the metal being liberated.

The fact, as shown in the preparation of metal [illegible] certain metals have greater affinity for each other than for certain other combinations, seems to make itself evident in the cohesion or attraction between the metal which is [illegible] deposited and the metal receiving it. It is held by some that

for the best adherence there should be a true alloying at the surface separating the two metals, and this appears to be borne out by microscopic examination of certain deposits. Zinc may form a very adherent coating on copper, due to the fact that the zinc alloys with the copper surface to a certain extent, and the poorer adhesion to iron may possibly be accounted for by a lesser affinity between two metals or, in other words, a lesser tendency to alloy. Gold will alloy very readily with zinc at ordinary temperatures, as shown by the very striking observation that a gold coating applied to a zinc

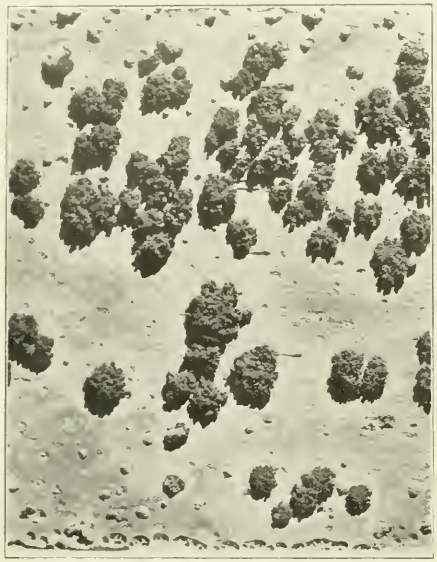

FIG. 5.—MOSS-LIKE GROWTHS ON ZINC CATHODES.

surface will in a few days entirely disappear, being absorbed by the zinc.

This alloying phenomenon, however, cannot be held as a universal one, for there are certain contradictory facts which must be taken into account. In many cases, one of which is the deposition of nickel on iron, there is no evidence for claiming that there is an alloying of the two metals, although a good adherent coating may be obtained. Further, if there is a tendency to alloy, it might naturally follow that the alloying would proceed indefinitely, and that the degree of adherence of the coating would increase with time. It is a matter of common observation, however, that many electrodeposited coatings become less adherent with time.

In fact, the theory of the alloying of the surface is not necessary in explaining the tenacity with which one metal will adhere to another, but a more satisfactory explanation is probably found in the direct cohesion which is established when solid particles are brought into intimate contact. Copper may be deposited in such a way that a cohesion between the copper particles themselves may be so great as to resist a force of 25 tons per square inch or over to separate them. If a copper particle is brought into intimate contact with an iron particle, a similar cohesion, though perhaps less in degree, will result. On this basis, therefore, it is desirable that in the electroplating processes the deposited metal should be brought into as intimate contact with the surface receiving the deposit as is possible. The adherence of a coating, as a consequence, will depend upon the amount of surface which is to be brought into contact.

It is well known that a surface which is somewhat rough will receive a more adherent coating than will a polished surface, and this is undoubtedly due largely to the greater amount of actual surface per superficial area which is brought into contact. Upon this supposition of the desirability of intimate contact of metal surfaces, the influence of the electrolyte on the adherence of a deposit may be explained. A surface which has had the proper physical treatment to prepare it for receiving a coating may have the appearance of being perfectly polished, but an examination by the microscope will reveal the fact that the surface is made up of minute particles with crevices between them. If, on immersing this surface into a plating solution, the solution penetrates into such crevices by passage of electric current, the metal will be deposited upon every point exposed to the solution. If, on the other hand, the solution is of such a nature that it will not go into these minute crevices, in which case the air or other insulating material will be retained therein, it is quite natural to suppose that it will be only the more elevated points which are in contact with the electrolyte. These points will receive the deposit, which will grow sidewise from these projections until the cavities are bridged over and the entire surface has the appearance of being coated. In this case it will be evident that the adherence of the coating will not be as great as it will be where the metal goes into the depressions.

As is well known, some solutions will "wet" a surface much more readily than will others, and in using a solution from which an adherent coating is to be obtained it is desired that the solution shall have the property of most thoroughly wetting the entire surface. Or, in other words, the electrolyte should consist of a solution in which there is a large mutual molecular attraction between the liquid and the metal surface. This property can be imparted to various solutions of metallic salts by the addition of certain other soluble substances, and

FIG. 6.—ROUGHENING OF IRON DEPOSIT.

it is for this reason that such additions are frequently practiced. It is easily shown that a coating of copper obtained by immersing aluminium in a copper chloride solution is very nonadherent, and may be readily brushed off; but that if an alcoholic solution of the same copper be employed, the coating is much more firmly adherent. This may, therefore, be explained on the supposition heretofore advanced that alcohol causes the copper solution to come into more intimate contact with all parts of the aluminium surface. In this connection, an investigation of the relation between the surface tension of solutions and various metallic surfaces upon the adherence of the coatings obtained would undoubtedly lead to some interesting results, and might establish guiding principles in the design of plating solutions.

The peculiar characteristic of all deposited coatings is that, no matter how dense, coherent and smooth the metal surface deposited may be, the cohesion and smoothness decrease with

time, and the surface eventually becomes rough. This is a serious limitation where thick deposits are desired, as in the electrolytic recovery and refining of metals.

Fig. 5 illustrates the appearance of moss-like growths on zinc cathodes. Fig. 6 illustrates a roughening of an iron deposition, and a phenomenon which frequently is observed is here shown, namely, the grooving or furrow characteristic. These grooves, which are almost always obtained in a vertical position, are due to the fact that the solution in the immediate neighborhood of the cathode, becoming depleted in metal, decreases in density and rises to the surface of the tank. The rising solution is, by the formation of small projections near the bottom of the anode, split up into columns of dilute solution, separated by columns of more dense solution. The electric current, finding a more ready path through the dense solution, deposits the metal more readily therefrom, and thus starts the ridges, after which the action becomes more pronounced. The remedy for this defect will be at once evident,

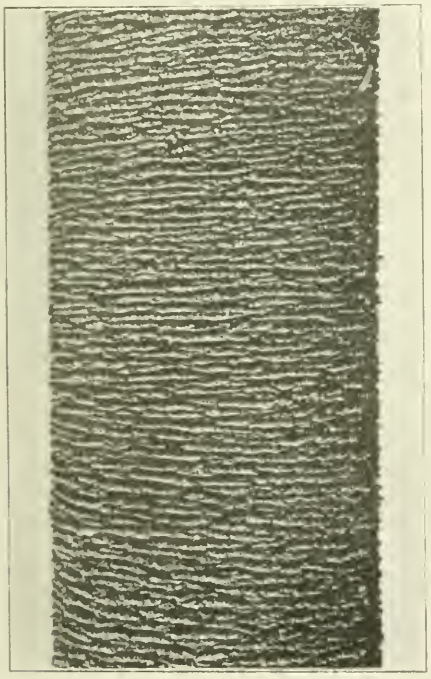

FIG. 7.—HORIZONTAL GROOVING, OBTAINED BY ROTATING A CYLINDRICAL CATHODE AROUND A VERTICAL AXIS, ZINC DEPOSIT

for, if the solution be agitated by stirring or other means, it may be prevented. This vertical position of the grooves is due to the fact that it has the same direction as the flow of the solution. An interesting example of horizontal grooving is illustrated in Fig. 7, where a cylindrical cathode was rotated around a vertical axis while receiving a deposit of zinc.

Fig 8 illustrates another effect which is frequently developed in electrodeposition, namely, the pitting or perforation of the metal. Perforations may be caused by the presence of insulating particles on the surface receiving the deposit by the deposition of particles of foreign substances which may be floating around in the solution, or by the liberation of bubbles of gas, which may adhere to the cathode. This defect is most commonly caused by the liberation of gaseous products, and the remedy is the choice of a solution from which such gas will not be liberated or by circulation or agitation of the solution.

These bubbles of gas, usually consisting of hydrogen, which may adhere to the cathode surface in sizes varying from most minute dimensions to one-eighth of an inch in diameter, insulate the surface at such points, and the metal may be built up around them, even completely inclosing them. This results in a porosity and inclusion of gas frequently found in deposited metals. Fig. 8 illustrates such pitting, and the wavy form which the metal takes around the lower portion of some of

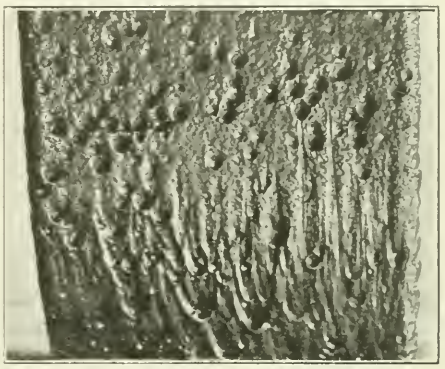

FIG. 8.—PERFORATION.

these cavities indicates the way the solution divides and flows around the obstructing gas bubbles.

Another peculiar property of electrolytic deposition, and one which makes itself particularly manifest in the separation of nickel, is the distortions in shape which certain deposits take after the deposition has proceeded to a certain thickness, or upon subsequent heating or other treatment of the metals. This is due to the strains which are set up during the process of deposition from the solution. It is claimed that nickel

FIG. 9.—NICKEL COATING, PEELING OFF.

deposited on a thermometer bulb will tend to contract with force sufficient to compress the glass and cause the mercury column to rise. This property becomes prominent in nickel plating where the coating is allowed to exceed a given thickness. These strains are such as to cause the nickel to tear away from the surface being plated, as is illustrated in Fig. 9.

LABORATORY OF APPLIED ELECTROCHEMISTRY,
University of Wisconsin.

## HISTORY AND PRESENT DEVELOPMENT OF ELECTROLYTIC NICKEL REFINING.

By Titus Ulke.

Probably the earliest attempt to electrolytically separate nickel from its alloys or matte, in any continuous or semi-continuous process of refining such substances, was made by Emil André, who obtained a German patent, No. 9,048, of November 1st, in 1877. André's process consists, briefly, in suspending nickel-copper bearing material, cast into plates, as anodes in an acid solution, and electrolytically depositing out most of the copper on cathode plates of sheet copper, and finally the balance of the copper on such plates, with carbon anodes put in place of the nickel copper anodes, this deposition occurring necessarily under varying and, therefore, in my opinion, commercially impracticable chemical and electrical conditions, then withdrawing the entire solution thus freed from copper, and recovering the nickel from same, after removal of any iron it contains and making it ammoniacal, by electro-deposition of the nickel on suitable cathodes and with (evidently unsuitable) anodes of ordinary iron or zinc. This process was tried in Germany and abandoned.

Not daunted by this and other failures, patents were obtained by Messrs. Basse & Selve, Ricketts, Hoepfner, Frasch, Browne, Ulke and others for the electrolytic separation of nickel or nickel salts from combinations of nickel with other metals or metalloids, and in some cases from ore, and works in Germany, Wales, Canada and the United States were erected, using processes based on several of these patents. In the following pages I shall now describe these interesting refining plants, to which visitors are almost invariably denied admission, as fully as the rather meagre data at my command will permit, treating the Vivian, Balbach, Cleveland, Hamilton and Papenburg Electrolytic Nickel Works in turn and ending with a discussion of the proposed copper and nickel refinery at Sault Ste. Marie.

### I. Vivian's Electrolytic Nickel-Copper Separating Works.

In 1892, according to Mr. A. F. Weightman, who kindly furnished me with the following data, H. H. Vivian & Co., of Swansea, Wales, started a new electrolytic copper refinery in connection with their nickel, cobalt and copper works, and introduced the recovery of nickel as a special feature of this plant.

In treating ores from Sudbury, Canada, containing nickel, cobalt and copper, by the "wet" process, at a certain stage of the latter large quantities of "residues" were obtained, which were melted down into anodes for electrolytic separation. These anode plates of nickel-copper alloy were placed in lead-lined depositing tanks, containing an acidified solution of copper sulphate, opposite copper cathodes. On passing an electric current, copper was alone deposited, and the solution therefore became richer in nickel and poorer in copper, until it was eventually withdrawn and treated especially for the recovery of the nickel.

The plant erected in Swansea was designed for the treatment of 10 tons of copper and nickel per week, but it never reached its full capacity, for reasons discussed later.

The anodes contained about 60 per cent. Cu and 40 per cent. Ni. As each pair of regular anodes and cathodes had one or two intermediate plates suspended between them, in series circuit, the system of refining used was based on a combined multiple and series arrangement of electrodes.

Forty tanks, loaded with plates thus arranged, and worked at a current density of 10 ampères per square foot, were installed, together with 10 tanks, known as "finishing" tanks, which were provided with lead anodes for the purpose of removing the last traces of copper from the solution.

The main tanks were arranged in pairs and each pair was supplied with solution independently. It was the company's aim to obtain good reguline copper in these tanks and to run off a liquor containing nickel and copper in the proportion of 9 to 1 into the finishing tanks, which would yield non-reguline copper. Experience soon showed, however, that this object could not then be attained, as the copper deposited in the main tanks was of a more or less non-reguline character and frequently "treed across" to the anode or to anode side of the "intermediate" plates and short-circuited the tanks. These tanks had to be repeatedly cleaned out on this account, and constantly required one man's time testing them with some form of voltmeter for short circuits. Whenever a tank short-circuited, the amount of copper in the solution escaping deposition in a given time and run into the finishing tanks, would quickly overtax the capacity of the latter. In the finishing tanks, as had been expected, the copper came down as a black, bulky powder, which accumulated in the bottom of the tanks rapidly and soon short-circuited the cells. In consequence it became necessary to clean them out every day, until a scheme to be described presently was adopted. The difficulty with short circuiting was so great that the actual output of the refinery was always much below its designed capacity, and this defect was further exaggerated by trouble with the dynamos. In those days British dynamo manufacturers were only accustomed to making machines for lighting purposes, in which the generator was only taxed to its full capacity for a few hours during the day, and ran the rest of the time on a light load. The result was that the machine supplied to the above works was quite inadequate to maintain a full load for weeks at a stretch and gave constant trouble during early stages, although more or less satisfactorily remedied subsequently.

The trouble from short-circuiting was considerably lessened by the following scheme introduced by Mr. Weightman in 1893, and recently patented, I believe, by Dr. Keith. As the solution in the finishing tanks got weaker and weaker in copper, the current density was continuously decreased, and this resulted in obtaining a more reguline deposit of copper and also in lessening the proportion of the refinery current wasted in evolving hydrogen, which occurred freely by the old method. Even with these improvements, the liquor could seldom be obtained sufficiently free from copper, i. e., with not over 0.1 per cent. Cu, which was the maximum allowable. Consequently the last traces of copper had to be "gassed down" with hydrogen sulphide, involving trouble and expense, and defeating largely the object of the process. Short-circuiting was also checked by casting the anodes somewhat smaller than the cathode sheets. This disposition not only removed the anode from that part of the system where "treeing" was the worst, namely, at the edges of the sheets, but it also checked the tendency to tree for the following reason: The distance the electric current had to travel from the edge of the anode to the edge of the cathode, since it had to take an oblique path, was greater than the distance between any other opposed portion of the electrodes, and consequently the resistance was greater. Therefore the current density at the edges was less than on any other part of the cathodes and the "treeing" was consequently checked.

The method adopted for stripping the cathode sheets from the cathode pattern plates consisted in varnishing the latter with a weak shellac varnish containing about 1 pound of shellac to 1 gallon of alcohol, which gave a coating sufficiently thick to prevent the copper deposited over it from sticking, and at the same time not thick enough to insulate the cathode from the passage of the current. The edges were dipped in "Brunswick black," and the pattern plates thus prepared, were hung in the cathode starting tanks to receive their copper deposits and form sheets, which were then easily detachable from their pattern plates.

An ordinary electric bell was found very convenient for testing the voltage of the cells. This bell was specially wound so as to ring at its ordinary loudness when the cells were at the correct voltage. If the bell rang more or less loudly it was a sign of either dirty contacts or short-circuiting in the particular cell under test. It was astonishing how exactly a man could tell the condition of a cell with this simple instru-

ment, and how much more it appealed to the average workmen than a delicately pivoted and expensive voltmeter.

In carrying out the above separating process, a very large amount of anode scrap was produced, which was expensive and troublesome to remelt, because of the high melting point of the Cu-Ni alloy. The amount was diminished by casting the anodes about 1/8 inch thicker at the top than the bottom (accomplished by setting the molds a little out of the level), and thus checking the tendency for the anodes to be eaten away at or near the surface of the electrolyte. The anodes were cast in closed molds and weighed about 80 to 90 pounds apiece. It was considered inadvisable to exceed this weight as most of the work in the cell room (in common with most English refineries) was done by manual labor, and any weight over 80 to 90 pounds was inconvenient to handle.

The copper-sulphate electrolyte was obtained by dissolving roasted matte by well-known methods and adding an excess of about 10 per cent. free sulphuric acid. The purified nickel-sulphate liquor from the cells, practically a saturated solution, was run off and boiled down until the anhydrous nickel sulphate separated out. This was then roasted to oxide and reduced to metal by carbon, although it was intended to eventually recover the nickel in a much purer state by electro deposition.

Small quantities of platinum were obtained in the anode slimes, but never in sufficient amount to be of appreciable account on the cost sheet.

The success of the above-described process was not considered sufficient to warrant its permanent establishment, and in 1894 the refinery was therefore closed.

### II. Balbach Electrolytic Nickel Refinery.

The largest and most successful electrolytic nickel refinery up to date appears to have been the one at the Balbach Works, Newark, N. J., erected in 1894 and operated until 1900, under the superintendence of Mr. F. A. Thum, who is believed to have originated the process employed there. Although this process has been jealously guarded as a secret by the Balbach company, and the exact conditions under which nickel refining may be successfully carried out practically were independently investigated and first published by others, the credit of being the pioneers in the commercial electrolytic refining of nickel as well as of copper in America undoubtedly belongs to the Balbach firm.

The analysis and mechanical tests of samples of nickel cathode made at the above works and seen by the writer indicated that the cathodes were remarkably pure and strong. The total absence of such elements as carbon, silicon and sulphur in the electrolytic product was accompanied by such good physical properties, particularly in the way of increased ductility, malleability and tensile strength, as to make it far superior in these respects to any fire-refined nickel I have ever tested. The only impurity, besides cobalt, found in the Balbach nickel was iron, and this only up to 0.25 per cent., which is certainly remarkable, in view of the close electrochemical relationship existing between these elements.

Although I had no occasion to see the Balbach plant in actual operation or to get any official information as to the composition of the electrolyte employed, I am convinced that the metal was produced by a process quite like that proposed by Prof. Foerster about three years ago in a communication published in the *Zeitschrift fur Elektrochemie*. In this process solid plates of pure metal to any required thickness may be deposited from neutral sulphate solutions heated to from 50 to 60° C.

The Balbach nickel cathodes had about the same dimensions and shape as the copper cathodes from the company's multiple system copper refining plant, showing that the same system and apparatus were probably applied in the refining of both metals.

The crude nickel anodes, assaying from 94 to 97 per cent. Ni, were furnished by the Orford Copper Co., of Constable Hook, N. J., and were reduced from their nickel oxide in a reverberatory furnace. The anode scrap and residues from the electrolytic process were returned to the Orford Works and put back into the nickel anode furnaces, to be returned again as anode to the Balbach Works and reworked electrolytically until the residues were at last rich enough in precious metals to make separate refining and parting profitable.

The above outlined process is not now in use there, as the Orford Co., upon whose nickel material the Balbach Co. were dependent, has ceased shipping crude nickel in the shape of anodes to the Balbach refinery, and is itself producing fairly good metallic nickel, averaging about 99.21 per cent. Ni; 0.66 per cent. C, Si, S, etc., and 0.13 per cent. Cu, by reduction of nickel oxide with carbon. This Orford nickel, however, being contaminated with carbon, silicon and sulphur, is neither as pure, nor as strong as good electro nickel obtained by the above process.

The Balbach nickel refinery was started in 1894, but its operation was discontinued about three years ago for reasons unknown to me, although I surmise that the large production of scrap from the imperfectly smelted and very brittle anodes was partly accountable for its closing down. The taking out of a patent by Mr. F. A. Thum for the electrolytic refining of nickel from metallic powder or granules, such as may easily be reduced from nickel oxide, to obviate the use of cast anodes, seems to point in that direction, and the same object of diminishing trouble with the anodes evidently also underlies the suggestion made by Mr. William Thum, also of Newark, to use slabs of crude nickel as electrodes in a series system, wherein the nickel deposited on the cathode side would make a staunch backing for the crumbling crude nickel of the anode side and thus obviate the difficult casting of anode suspension and contact lugs. It is claimed that electrolytic nickel can be produced from Orford anodes in this way at a cost of less than 1 cent per pound.

Besides metallic nickel, the Balbach Smelting Co. have been a heavy producer of nickel plater's salts. Such salts have been profitably recovered, for the last twelve years, as by-products in processes for the regeneration of its foul electrolytes from the company's copper refinery, the small quantities of nickel contained in the blister copper treated being all retained in the acid electrolyte and, of course, concentrating therein.

The Balbach method of recovering the nickel sulphate consists chiefly in repeated fractional crystallizations and a final removal of the remaining copper by electrolysis.

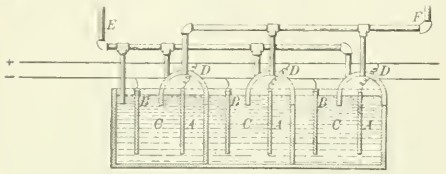
### III. Cleveland Nickel and Copper Refinery.

This refinery developed from an experimental electrolytic plant started six or more years ago in the Brooklyn suburb of Cleveland, Ohio, by the Canadian Copper Co.

The commercial plant, operating under a Canadian patent of Mr. David H. Browne, No. 74,401 of January 14, 1902, reissue of No. 69,729 of December 21, 1900, in 1902 began to produce, and turned out from 8 to 15 tons of electrolytic nickel per month, but closed down several months ago, I presume, temporarily.

Mr. Browne's electrolytic process consists of the following steps: Anodes of copper-nickel alloy and cathodes of pure copper are suspended in a solution of copper-nickel chlorides which is continuously regenerated by passing it through a tower filled with Bessemerized matte or alloy to be treated, in contact with salt solution and chlorine gas evolved from the nickel precipitating process. When the electrolyte is rich in nickel, and the copper nearly all deposited on the copper cathode, the remaining copper is probably gassed down with hydrogen sulphide and removed, the iron precipitated with ammonia and filtered off, and the hot neutral nickel chloride solution remaining, electrolyzed in contact with carbon anodes

in a water-sealed compartment (See Fig. 1.), and pure sheet nickel cathodes. The chlorine evolved from the anode compartment is conveyed to the regenerating tower to assist in



BROWNE'S ELECTROLYTIC PROCESS FOR THE ELECTROLYTIC SEPARATION OF NICKEL AND COPPER.

dissolving additional nickel and copper from the material that is treated. It is rumored that the erection of larger works, operating as above outlined, at a more suitable location, is contemplated.

### IV. Hamilton Nickel-Copper Refinery.

This plant was built about three years ago at Hamilton, Ontario, and consists of a frame tank house, about 40 feet wide and 100 feet long, containing, it is reported, about 40 depositing tanks, laboratory, supply tanks, etc., and storehouses. It was originally built to treat Sudbury ore by the Hoepfner process, but was remodeled later to accommodate the Frasch process and apparatus.

As described in the *Engineering and Mining Journal* of September, 8, 1900, and applied to copper-nickel matte, Frasch's process consists essentially "in the electrolysis of a brine solution, so as to produce caustic soda solution in the cathode section of a divided electrolytic tank, and chlorine in the anode section, in which is placed the nickel-copper matte, the metals in the latter being dissolved and forming chlorides.

"The copper in the solution thus obtained is recovered by electro-deposition, the nickel being separated from the cobalt, iron, and the remaining traces of copper as a double salt of nickel and ammonia, while the caustic alkali is recovered from the solution withdrawn from the cathode section as a by-product. The matte, coarsely crushed, is charged directly on a layer of carbonaceous material in the anode section of the tank, and is covered by a thin layer of sand, which is said to make a very satisfactory diaphragm for the separation of the resultant solutions of caustic soda and the chlorides of the metals. The tank is now filled with brine which is then electrolyzed, and the metallic solution obtained in the anode section and the alkaline solution in the cathode section are periodically displaced by fresh salt solution.

"When it is decided that the nickel-copper matte on the bottom of the tank has received sufficient treatment to require removal of the solid residue, the upper layer of sand is taken out and washed for re-use, and the leached or partly leached material removed."

Hoepfner's and Frasch's processes were both tried within the last two or three years, on a small commercial scale in the Hamilton refinery, but neither of them attained practical prominence. The plant owned by the Hamilton Nickel Co. has at present closed down.

### V. Papenburg Nickel-Copper Refinery.

The Papenburg electrolytic works, belonging to the Allgemeine Elektro Metallurgische Gesellschaft at Papenburg an der Ems, Germany, are said to be producing a small output of copper and nickel, according to a modified Hoepfner process, using a chloride solution. It is stated that the capacity of the works is about 1 ton of refined copper daily, and the same quantity of electro nickel, although the actual output is certainly considerably less than this amount.

The process is applied particularly to ores and matte, these being leached with a cupric chloride solution, so as to dissolve their copper, lead, nickel and silver contents, and simultaneously reduce the cupric salt to the cuprous state. After purification and being freed from silver, the solution is passed into electrolytic cells with carbon anodes and copper cathodes. Chlorine is liberated at the anodes and utilized, and the cupric and nickelic solution remaining after electrolysis is withdrawn, freed from copper, its nickel contents recovered electrolytically, and the remaining solution re-used in leaching a fresh charge of ore or matte. Very recent reports indicate that the Papenburg concern has not yet achieved commercially successful results, that for all practical purposes Hoepfner's original process has been abandoned and that the entire plant is being remodeled.

### VI. Proposed Sault Ste. Marie Copper and Nickel Refinery.

The Consolidated Lake Superior Co. propose the erection of a large copper and nickel smelting and refining works at Sault Ste. Marie, either on the Michigan or on the Algoma side. Plans and estimates have been prepared for a plant with a daily productive capacity of 75 tons of fine copper, 7.5 tons of fine nickel and for refining the precious metals contained in the material to be treated, according to my improved process and plant. The works are designed especially for treating anodes of crude nickeliferous copper, averaging, say, 88 per cent. Cu, 8.8 per cent. Ni, and, say, 20 ozs. Ag. per ton. These nickeliferous anodes may be secured by adding a certain tonnage of Sudbury matte to at least double this quantity of Lake "mineral," slagging off the iron silicate, removing the sulphur, refining up to the desired point and finally casting the product into anodes. I would recommend the employment of Mr. Thum's electrode

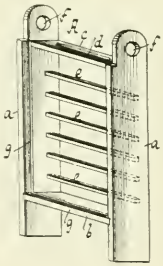


FIG. 1.

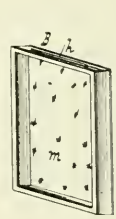

FIG. 2.

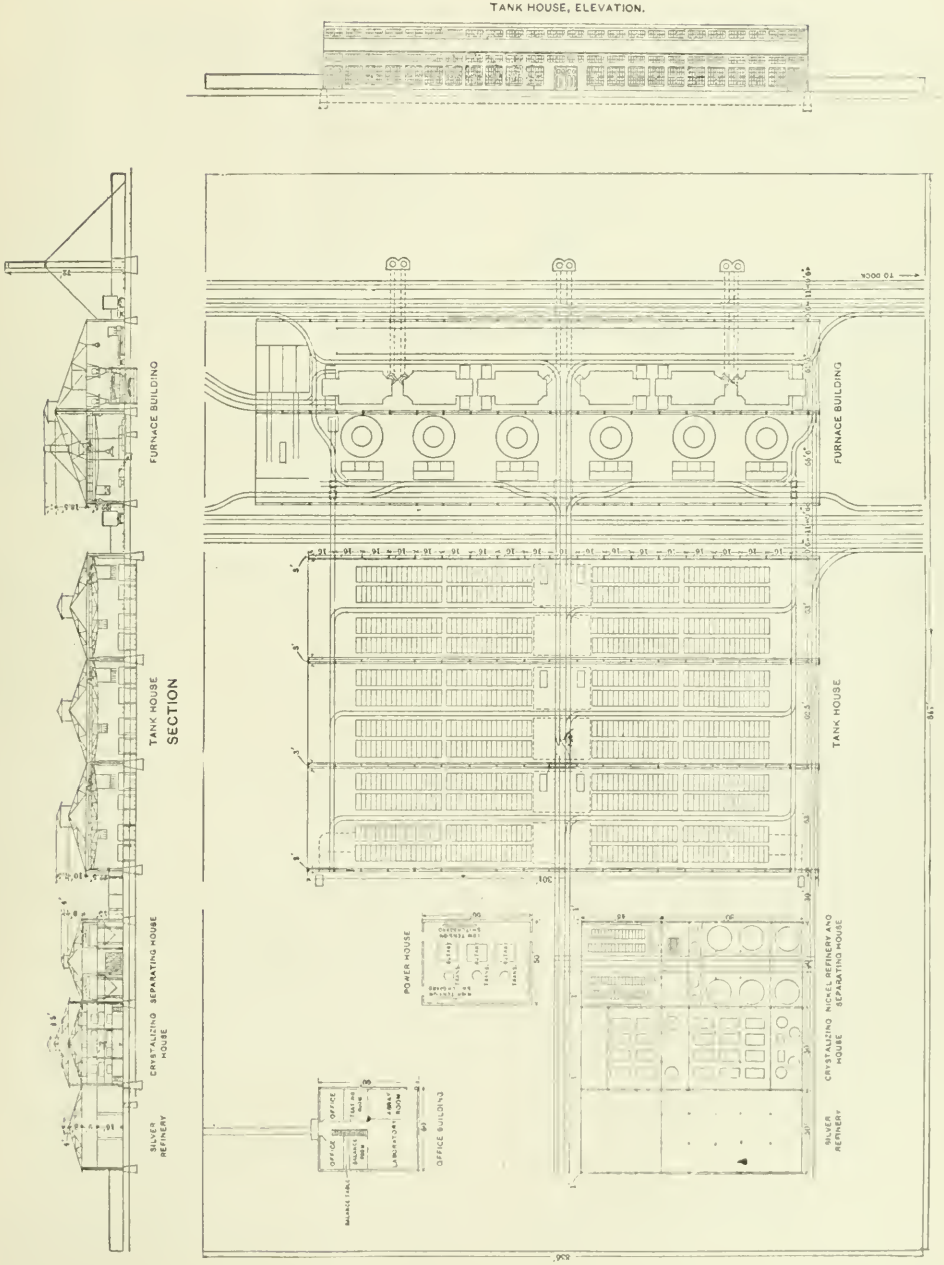
FIG. 3.

THUM'S ELECTROLYTIC APPARATUS.

frame, described later, in connection with my improved process for the separation and electro-deposition of nickel. This combination method would then embody the reduction of the nickel sulphate obtained in the second stage of my process to the granular, semi-metallic, or "reduced black-oxide" state, and the use of this material instead of lead, as an anode. The reduction of nickel sulphate or oxide with carbon to granular nickel takes place at a low temperature, while reduction and fusion to a *solid* nickel anode requires a high temperature and is therefore much more expensive than the process advocated.

The neutrality of the electrolyte must in every case be carefully maintained, for if it is not kept constantly neutral or approximately so, and is allowed to change from an acid to an alkaline reaction or *vice versa* deposition, the electro-depositing nickel is apt to peel off and cause trouble.

The apparatus for depositing nickel described in Mr. F. A. Thum's U. S. patent No. 614,633 of November 22, 1898, as applied to nickel refining, consists essentially of a non-conducting frame A and B (see Figs. 1, 2 and 4), adapted to hold the finely powdered or granular nickeliferous material to be refined, said frame being closed at the side facing the positive conductor by a removable plate of nickel or a greased sheet of copper, and at the opposite side by a diaphragm of muslin or other suitable material. A number of such frames or elements are assembled in an electrolytic tank and arranged according



DESIGN OF PROPOSED COPPER AND NICKEL REFINERY.

the series process (see Fig. 5), the positive current being conducted to the material to be refined, which serves as an anode, of the first element of the series, and the negative current taken away from the cathode plate or sheet of the last element, without the intervention of any intermediate conductors excepting the elements themselves. At the top of the frame is a charging opening for supplying the anode material. In detail, the frame A is formed of side pieces *aa*, bottom *b* with grooves *g*, top *c* with opening *d* and cross bars *ee*, while B is provided with an opening *h* at the top and is closed at the outer end by a diaphragm of muslin or other suitable material *m*. Frame B is inserted into the frame A, so that the diaphragm *m* is supported by the cross bars *ee* and the opening *h* is beneath the opening *d*. The element is completed, finally,

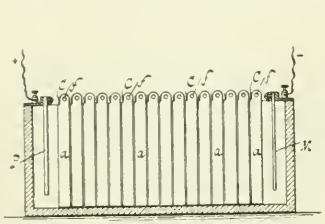


FIG. 5.

FIG. 4.

THUM'S ELECTROLYTIC APPARATUS.

by a plate C of metal, such as nickel or copper, which is slightly greased and inserted into the grooves *g*, and serves as a receiver for the deposited electrolytic nickel.

When a suitable electric current is passed through the tank, filled as it is with a hot neutral solution of nickel sulphate and the electrodes as described, the anode material is dissolved on the diaphragm side and the nickel is deposited on the opposite cathode plate. As soon as the deposit has reached a sufficient thickness, it is removed and melted into ingots, or utilized, as I prefer, without melting, as the latter process is apt to introduce injurious impurities into the nickel.

Whenever there is a settlement of the material in the casing, fresh material may be charged through the openings *d* and *h*. From time to time the elements are in rotation removed from the tank, the deposits stripped from the plates C, the residue within the casing emptied, and the casing refilled.

### CONCLUSION.

In the processes for the electro-deposition of nickel with insoluble anodes no very recent progress has been shown. When the metal is recovered on a large scale by the aid of soluble anodes, the electrolyte is kept constantly at a predetermined degree of saturation and at the point of neutrality, on which condition largely depends the nature of the deposit and the commercial success of the process. When insoluble anodes are used in refining nickel, however, an equivalent of free acid is left in the electrolyte for every equivalent of metal deposited, and in consequence the nickel deposit is apt to deteriorate, the chemical and electrical conditions of the bath are changed, polarization ensues and the resistance of the electrolyte increases. This, of course, means that the voltage and power required must be increased proportionately, and the cost of refining with insoluble anodes may thus become next to prohibitory, as compared with a similar process using soluble anodes. These and other difficulties have been the chief reasons why our electrochemists, instead of making pure metallic nickel by electrodeposition, preferred to work the nickel solutions into marketable sulphates, double sulphates and chlorides, which have had a ready sale until recently, but which now seem likely to become a drug on the market, just as copper-sulphate was before the adoption of electrolytic refining methods.

Permit me to say, in closing, that if any of the above-made suggestions will aid in improving the technical practice and commercial success of my co-workers in this interesting and fertile field of electrochemical work, the object of this paper will have been fully attained.

## NOTES ON PHYSICAL CHARACTERISTICS OF ELECTRODEPOSITED METALS.

By Woolsey McA. Johnson.

This subject has never been adequately treated in any book on electrochemistry, either theoretical or practical. We find in the literature a mass of experimental evidence, but no attempt has been made to collect it and to classify it. Consequently the explanations of the varied phenomenon are always of a special nature.

In the limits of this short article it is impossible to give any general scheme, but it was thought that an investigation of why in one case the deposit is good and in another case the deposit is poor will help others to systematize our knowledge and tell us the reason for the facts as we know them.

One of the first things observed in studying this question is that in electroplating "double salts" are often used, and usually with excellent results.

The modern theory of electrolytic dissociation has developed some remarkable facts about these double salts, or, as it calls the resultants of them, "complex ions." We know, for example, that it is possible to reverse a Daniell cell by simply adding a strong solution of KCN to the catholyte; that this will give a steady discharge of a considerable current, with the copper dissolving and the zinc being precipitated.

By Nernst's equation we have

$$E = e_1 - e_2 = 0.058 \log. \frac{Pzn}{pzn} - 0.058 \log. \frac{Pcu}{pcu}$$

neglecting the small e. m. f. at the contact of the solutions.

Now, when we add KCN to catholyte, we do not affect Pzn or pzn or Pcu, but we reduce Pcu to a small value. In other words, we have decreased the ionic pressure of copper to an amount so small that its own solution pressure is sufficient to push the copper ions continually into solution. Copper hydrate is, for analytical purposes, considered insoluble, but the solution pressure of $Cu(OH)_2$ with regard to the copper ions is large compared to that of the potassium copper-cyanide that is formed.

Similarly, we find that in a "concentration cell" that reagent which produces a chemical action in precipitating a dissolved salt or in dissolving a precipitate gives a higher e. m. f. against the standard electrode.

To be concrete, the cell

Ag|AgNO$_3$ 0.1m|AgCl nKCl|Ag gave 0. 54 volt.
Ag|AgNO$_3$ 0.1m AgNO$_3$, nNH$_4$OH|Ag gave 0.54 volt.
Ag|AgNO$_3$ 0.1m AgBr nKBr|Ag gave 0.64 volt.
Ag|AgNO$_3$ 0.1m|AgNO$_3$ Na$_2$S$_2$O$_3$|Ag gave 0.84 volt.
Ag|AgNO$_3$ 0.1m AgI KI|Ag gave 0.91 volt.
Ag|AgNO$_3$ 0.1m AgNO$_3$ KCN|Ag gave 1.31 volt.
Ag|AgNO$_3$ 0.1m AgNO$_3$ Na$_2$S|Ag gave 1.36 volt.

We can see that each reagent in the electrochemical series produces a chemical action on the compound just below it. For instance, AgCl is soluble in NH$_4$OH, while AgBr is precipitated by the action of KBr on the soluble ammoniacal silver salt. The same is seen through the series $Na_2S_2O_3$, KI, KCN, $Na_2S$. His knowledge throws a Nernst light on the subject. We find in the ionic theory of concentration cells a satisfactory explanation for the perfect correspondence between chemical behavior and the electrochemical quantity, e. m. f. against a standard electrode. The same correspondence is found true in most concentration cells measured. For further particulars, the reader is referred to Nernst's classical researches on concentration cells, in the *Zeit. f. Phys. Chemie*, 1889, or to Le Blanc's "Elements of Electrochemistry" (translated by W. R. Whitney), p. 178.

It is therefore quite easy to understand why NH$_4$OH dissolves AgCl, etc. It is that a double salt is formed by the two,

which has such a small pressure of silver ions that the reaction proceeds until equilibrium is reached. Looked at broadly, it is little different from the rising of heated air or the flowing of water down-hill. All three actions consist in matter flowing from high pressure to low pressure. The difference lies in us. Water pressure and air pressure are familiar to our minds, but an ion pressure is a new conception.

As is well known, these double salts are found useful to the electroplater. We need only instance the nickel bath of double nickel ammonium sulphate and the silver bath of the soluble potassium silver cyanide. (In electroanalysis Professor Classen has made use of the double ammonium oxalates, etc.)

The value of these double salts is connected in several ways with the formation of complex ions. In the first place, they render necessary a high voltage. Take silver plating, for example. If a solution of silver nitrate were used, we could deposit silver at a very low "electrode voltage." By using the solution of $KAg(CN)_2$, we use a voltage higher by 1.20 volts. The ions are hurled out of the solution under great pressure. The following analogy illustrates this point. To be a bit slangy, we will consider a boy throwing snow at the shingled side of a house. If he tosses it gently, it is not apt to stick, unless it is very sticky snow; but if he gets off 10 feet and "slugs" snowballs at it, the snow is pretty sure to get in between the cracks and stay there. Naturally, with a high electrode voltage, we are apt to have good, solid, adherent deposits. By this term, "electrode voltage," is not meant the voltage across the terminals of the vat, but the voltage of the electrode against a standard electrode. In other words, we measure the electromotive force with which the cations are drawn from the catholyte to the cathode. This voltage can be measured by a potentiometer if we use the hydrogen electrode, or, in case we use a electrode which will not polarize with a current of several milliampères, by a Weston voltmeter.

The necessity of distinguishing between "electrode voltage" and "terminal voltage" cannot be too strongly emphasized.

Both "terminal voltage" and current density are useful terms in their place, but they do not tell us much about the electrochemical reactions which are taking place. "Electrode voltage," or "electrode potential," to use the more correct term, is the quantity that should be measured. Suppose we are refining a copper anode carrying gold values. We find that, with a certain current density and a certain solution, we have a slime carrying 99.5 per cent. of the gold in the anode. Now, if we substituted for the copper anode a silver anode carrying the same amount of gold, we should find that quite a considerable portion of gold would be carried to the cathode. Measurement with the potentiometer against a hydrogen electrode would show the reason for the discrepancy in the difference of readings. The question of surface is a large factor. Some anodes are porous, and, on dissolution, present a larger surface to the current than measurements would indicate. Again, the current density is not uniform. The anode surface is not constant in chemical composition. It has been known for thirty odd years that the silver in copper concentrates in an outside layer. A few of these facts are mentioned to show that in electrolytic works conditions are rarely such as they are supposed at first glance, and the "electrode potentiometer" is a good instrument to use when we wish to learn bottom facts and with which to diagnose these unknown variations.

The writer was at one time employed in experimental electrorefining. It was found possible to gradually run the slimes from 4-ounce precious metals to 15-ounce, 28-ounce, 78-ounce successively. The potentiometer method of measuring the e. m. f. of the anode against the standard electrode was the best help that could be found whenever trouble arose.

The same method is of value in telling us what happens electrochemically at the cathode. The reading of potentiometer gives us exactly the relative forces which pull the cations out of the solution.

We know that it is necessary to have also a good supply of cations present in the catholyte, as well as to have a high "electrode voltage" of deposition. If a single salt were used, we should be obliged to use a concentrated solution to attain this condition. To use a high electrode potential in depositing, we should be obliged to use with a single salt a high current density. This would mean that the catholyte would be quickly impoverished of cations. In accordance with these facts, we find that all successful processes for making springy and elastic electro copper in sheets use fairly high current density, strong solutions and keep the catholyte constant by some means of circulation. Just here is where the double salt, with its complex ion, plays an important *rôle*. It causes a high e. m. f. to be used in depositing, and it furnishes the catholyte with a good supply of cations by its continuous decomposition. A good electrodeposit is therefore obtained from the double salt for good electrochemical reasons.

The function of the double salt, in preserving a fairly constant cation concentration, is in line with the importance of concentration changes, as shown in the working of the lead accumulator.

The solution which has undergone electrolysis undergoes often permanent chemical changes, forming basic insoluble salts. These salts are either held partly or entirely in solution by the double salt.

In storage-battery work it is found that the bottom of a plate ages faster than the top of the plate. Analyze the top layer of the electrolyte and the bottom layer, and it will be found that the bottom becomes concentrated and the top dilute. This makes a non-uniform current density, and causes thereby lowered efficiency, because of local action of the vertical "concentration cell" set up.

In electrodeposition we use much higher current density and we have a soluble anode, while in the lead accumulator both electrodes gain in weight on discharge and lose in weight on charge. The action of a soluble anode is partly reversible, as in the lead accumulator. The irreversibility depends largely on these concentration changes. To counteract these changes and to keep the electrolyte of uniform composition is the function of the numerous devices for circulating the electrolyte, by blowing air through it, forcing the solution in a jet at the cathode or by moving the cathode, etc. A good part of the advantage found in hot solutions is due to the fact that they necessitate some circulation.

The effect of these concentration changes on the character of the bath is often permanent, as remarked above. If we use a high current density in electrolyzing the nickel bath, we have the formation of nickelic sulphate in the anolyte, and of nickelous hydroxide or basic sulphate in the catholyte. These last two compounds are, of course, insoluble in neutral solutions, and very slowly soluble in dilute acid solutions. They form a slime which renders the solution turbid, falls to the bottom of the vat, or, in extreme cases, will form a thick apple green paint on the cathode.

By the electrochemical reaction above described the electrolyte becomes acid, and we have a "gasing" at the cathode, as the velocity of counter reaction is slow. In the old Balbach nickel refining process this sludge used to collect in the "well." By stirring this sludge with electrolyte which had grown acid, the solution was kept near the neutral point. Similar phenomena have been observed by the writer in electrolyzing iron or ferro-nickel. In one case a beautiful, dull, silver white deposit will be obtained, while on a slight increase in current density the solution will have an insoluble sludge of dirty brown basic salt. The change is a very sharp one.

The formation of a cloudy precipitate or the presence of suspended particles of any kind from anode slime has, as is well known, a bad effect on the physical characteristics of electrodeposited metals. These particles have in few cases a conductivity exactly equal to that of the deposited metal, and, of course, in the case of basic salts are insulators. When adhering, as they often do, to the cathode, they cause a local distortion of the electrochemical field. The lines of force are hunted round this particle and build up the deposit at the

outer edge with great rapidity as the current density is large there. These nodules, if allowed to grow, grow *"ipso facto"* with great rapidity and spoil the deposit, making it porous and brittle, and in the case of thick deposits "warty" and poor. A hydrogen bubble will cause the same trouble. The solution can be kept clear of these suspended particles by running through a filter or filter press, or allowing to settle in outside vat.

The use of a hot solution is bad, in that it accelerates the formation of these basic salts. For nickel, the use of a hot solution is often recommended, and this fact has been known for years. In fact, a Bristol, Conn., plater was using it practically in 1888. The work of Foerster showed that for depositing thick sheets the hot (50° to 60° C.) solution was desirable. Since Foerster's work it is often stated that it is impossible to deposit a thick coating of nickel from a cold solution. Perhaps the best piece of deposited nickel the writer has every seen was on the wires suspending a plater's basket. It was three-quarters of an inch thick, hard as steel and shone with a dull silver finish. A small current density was used, and this was the cause of the excellence of the deposit. This deposit was made from a cold solution.

The reason why electrodeposited nickel "curls up" (which is said to be prevented by hot solutions, but is only prevented in certain cases) is due, in the opinion of the writer, to the tremendous molecular strain under which nickel, or rather the nickel-hydrogen alloy, is deposited. We can obtain some idea of this by the fact that the electrodeposited nickel is electropositive to cast nickel by 0.25 to 0.05 volt, according to the potential at which it was deposited. This shows that the molecules are placed under an abnormal strain. Another bit of evidence proves this physically.

Nickel was electrodeposited on a malleable nickel cathode sheet, 18 x 12 inches, which fitted in a groove in the end vat, which was 12¼ inches wide. The groove was made of slats, ½ x ½ inch in cross section, nailed to the vat and painted with asphalt paint. The surface exposed was about 18 x 11⅛ inches. At the end of six days' deposit out of a hot solution, the electrolytic sheet, still adhering to the soft sheet, was wedged in so strongly that two men were required to pull it out. The whole sheet was now elastic. In addition to the potential energy of electrolytic solution, as measured by the potentiometer, there was also the potential energy of an elastic body under strain.

Now, it will be found that both these physical quantities diminish with time, and also with temperature. Take pure electrolytic nickel (by electrolytic nickel, of course, is meant nickel alloyed with an amount of hydrogen) and anneal it in a Bunsen flame. It loses both its elasticity and its "overvoltage." Allow it to stand, and it will gradually lose these same properties.

The "curling up" of electrolytic nickel is probably caused by the fact that there is an unequal strain between the inside and outside layer. The inside layer, when deposited, had the same abnormal strain, but with time this tension has become more normal by a slow annealing action. The outside layer has had, however, no time for the molecules to adjust themselves, and consequently the tension is greater on the outside than on the inside. Electrodeposited nickel tears itself from the cathode and curls up, just as a piece of paper curls up in drying, which is undoubtedly due to unequal strains of the inside and outside layers. The curling is always such that the outside layer is on the concave side of the bending.

It is also a fact that the contact to the original cathode will determine to a large extent whether the electrolytic nickel curls or not. For instance, if the plating be on a rough or matted surface, it will stick to this cathode when it would not stick to a smooth cathode. Nickel will stick to a clean, smooth surface when it will curl from the same surface which is oiled or graphitized. When a large current density is used, nickel will often stick to the sheet, but the whole plate will curl up unless the deposit be on both sides. If the current be interrupted for a short time and then continued, the nickel deposit will in many cases curl up where film of oxide, formed during interruption, has made a plane of weakness. Further facts could be adduced to point to the same conclusion—that the curling up of electrodeposited nickel is due to the unequal strains between outside and inside layers, and that hot solutions and low electrode voltage, which have been found to be favorable, are favorable because they tend to equalize these strains.

In conclusion it may be said that there are few better fields for investigation than that indicated in the title of this article. If such divigations as these lead anyone to explore this field thoroughly, the writer will feel more than repaid for putting his modest views before the electrochemical world.

Sidney, C. B., January 28th.

---

## PIONEERS OF ELECTROCHEMISTRY—V.

### Wilhelm Ostwald.

In one of his lectures on "Physical Chemistry," held at the celebration of the tenth anniversary of the University of Chicago, J. H. van't Hoff, while reviewing the historical development of physical chemistry, makes the following remark: "It is a rather small number of those who, working not always under the most favorable conditions, have contributed during the last fifteen years to the development of physical chemistry. Ostwald must be mentioned first, who, by his comprehensive activity as a teacher, by his surprising literary work, and by his talent as an organizer, has probably done more for the development of physical chemistry than many others."

A good deal of the work of Prof. Ostwald has had to do with electrochemistry, and he was indeed a directing force in the development of modern theoretical electrochemistry on the basis of the so-called theory of electrolytic dissociation. Even those who think that here too large a building was erected on too narrow a basis have never denied the "inspiring atmosphere of Ostwald's laboratory," and there is nobody who would not admit that Ostwald's work has done a great amount of good in stimulating and directing researches which are certain to bring fruits in the further development of electrochemical science and industry. It is thus highly appropriate that his name should be placed here among the pioneers of electrochemistry.

Wilhelm Ostwald was born in Riga, Russia, on August 21 (September 2d), 1853, as the son of a cooper. After having passed through a grammar school, he visited the Realgymnasium at Riga, from which he was graduated in 1871. As a boy he was mechanically inclined and his father wanted him to become an engineer, and was somewhat sorry that his son insisted on a purely scientific career. In January, 1872, he entered the University of Dorpat and studied for three years chemistry and physics, his most adored professors being C. Schmidt, A. von Oettingen, and Joh. Lemberg. In 1875 he became assistant in the physical laboratory of the university.

In the same year (1875) he published his first investigation on the mass action of water (*Jour. f. Prakt. Chemie*). In 1876 he published in the same journal a paper on volumetric chemical studies. The same subject was dealt with in the thesis for his master's degree (1877), and in the thesis for the degree of doctor of philosophy (1878). In 1878 he began his work as a university teacher by lecturing, two hours a week, on the theory of chemical affinity.

In the following years he published quite a series of papers on the subject of chemical affinity. Having been assistant in the chemical laboratory since 1875, he became in 1880 assistant in the physical laboratory. In the same year he married.

In the autumn of 1881, Ostwald became professor of chemistry in the Institute of Technology of Riga, the city of his birth. Here he remained for six years, and in this period his

Lehrbuch der Allgemeinen Chemie" was written (1883 to 1886). Shortly after this well known work had been finished, he, in conjunction with Prof. van't Hoff, founded in the spring of 1887 the *Zeitschrift f. Physikalische Chemie*.

In the autumn of 1887, Ostwald was called to the University of Leipzig, where he still remains as professor of chemistry, in special charge of the branch of physical chemistry. It was here that he developed his enormous activity.

Besides his papers published in various journals, but mainly in the *Zeitschrift f. Phys. Chemie*, Ostwald has written the following books: "Grundriss der Allgemeinen Chemie" (1889, 1890, 1899); "Lehrbuch" (1883-89, 1891); "Hand-und Hilfsbuch" (1893, 1902); "Geschichte der Elektrochemie" (1894-95); "Wissenschaftliche Grundlagen der Analytischen Chemie" (1894, 1897, 1901); "Aeltere Geschichte der Lehre von den Berührungswirkungen" (1898); "Grundlinen der Anorganischen Chemie" (1900).

In 1901 Ostwald founded the *Annalen f. Naturphilosophie*. Since 1883 he is the editor of the well-known series "Klassiker der Exakten Wissenschaften." In 1892 he published a German translation of Gibbs' fundamental thermodynamical papers. These papers, buried before in scarcely accessible transactions, became thus accessible to the general scientific public, and the German Ostwald was thus instrumental in making known the name of the greatest thermodynamical scientist of the United States. In 1897 and 1898 a new laboratory was built, according to the suggestion of Ostwald. The enormous work, done by his students in the old laboratory under his direction, and according to his suggestions, may be appreciated from the collection of their papers in four volumes.

In 1893 Ostwald founded the German Electrochemical Society. He was its recognized soul and heart, and to him is also due the recent change of the name into German Bunsen Society, which name was chosen to indicate the broader scope of physical chemistry in general.

In spite of his pronounced scientific progressiveness, Professor Ostwald possesses that conservative spirit which is achieved by the historical study of the development of science. Although firmly fixed in his scientific convictions, he is no fanatic. In the German Electrochemical Society he always advocated the co-operation of theorists and practical men. The number of his old students is legion; they are found wherever physical chemistry and electrochemistry are taught or applied, in universities and schools, as well as in the laboratories of chemical manufacturers, not only in Germany, but all over the world.

May Geheimrat Ostwald continue his fruitful activity for many years to come.

# ANALYSIS OF CURRENT ELECTROCHEMICAL PATENTS.

By George P. Scholl.

APPARATUS AND PROCESSES FOR THE ELECTROLYTIC PRODUCTION OF METALS AND COMPOUNDS.

*Manufacture of Chlorates.* R. Threlfall, Birmingham, England. Patent No. 710,780, December 23, 1902. Application filed May 2, 1902.

The inventor claims to have discovered that in order to obtain a high current efficiency in the manufacture of chlorates it is necessary to have a certain amount of free hypochlorous acid always present in the electrolyte, preferably about two grams HClO per liter. He proposes to obtain this by splitting off a part of the electrolyzing current and diverting it to an auxiliary cathode, arranged in a suitable porous vessel, either inside or outside the main electrolytic vat. There is thus more chlorine formed at the main anode than alkali at the main cathode, and the excess of chlorine at the anode is said to react with the hypochloride present in the electrolyte, according to the equation $RClO + H_2O + 2Cl = RCl + HClO_3$, R designating one atom of an alkali metal. HClO spontaneously breaks up as follows: $3HClO = 2HCl + HClO_3$ and $HClO + RClO = RCl + HClO_3$, the two reactions being continuously repeated. Electrolysis in the main vessel takes place without a diaphragm; the anode is preferably made of platinum or platinum alloys, and the cathode either of the same materials or of carbon. A regulating resistance is arranged in the path of the current to the auxiliary cathode, in order to stop or vary the action. With a current of 1,000 ampères, about 950 amperes pass to the main cathode and the remaining 50 amperes to the auxiliary cathode. Approximately 90 per cent. of the theoretical yield of chlorate is said to be obtainable by this process.

*Apparatus for Producing Caustic Soda by Electrolysis.* E. A. Allen, Rumford Falls, Me., and H. K. Moore, Lynn, Mass. Patent No. 710,804, December 23, 1902. Application filed December 27, 1898.

Fig. 1 shows a cross section of the apparatus. The underlying principle of its construction is the same as the Hargreaves apparatus, namely, the arrangement of the cathode on the outside of a diaphragm, and not in direct contact with the electrolyte. The cell has two end walls, connected at their upper ends by two bars $a^4$ $a^4$, thus leaving the longitudinal sides entirely open. The open sides are closed by a diaphragm *b* of asbestos paper or other substance, which will permit the free percolation of the electrolyte. On the outside of each diaphragm is arranged the cathode *c*, consisting of a series of layers of wire cloth or a bed of steel wool, in the form of a

comparatively thick sponge. The asbestos paper and the wire sponge are bent under the bottom plate, in order to make electrical contact with the long iron plate *d*, upon which the cells rest side by side. The anode consists of pieces of gas carbon *c* cast in a lead frame *c*¹. A sheet lead jacket *f* dips into a groove *a*¹, filled with any suitable non-volatile hydrocarbon, such as coal tar, to form a seal for the chlorine. Suitable openings, capped by a glass dome *g*, are left in the cover of the cell to conduct the chlorine away. The plate *d*, which is connected with the source of the current, is inclined and provided with a trough at its lower edge, in order to receive the fluid resulting from the electrolysis. During electrolysis the solution percolating through the diaphragm trickles down through the cathode sponge from top to bottom, being constantly exposed to the action of the current on its way down, with the result that it reaches the plate *d* in the consistency of molasses and consists of caustic soda with only a small percentage of sodium chloride. It is stated that a current density of not less than 444 nor over 510 ampères per square meter of cathode surface produces the best results, and the diaphragm should preferably be made to permit a percolation of about 3 liters to each square meter of diaphragm surface in one hour. The temperature of the cell should not be increased above 80° C.

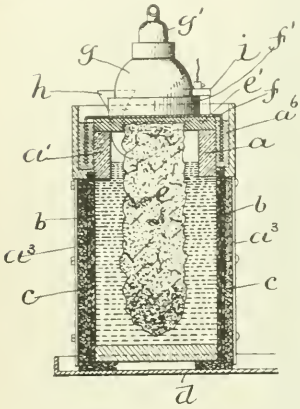

FIG. 1.—CAUSTIC SODA APPARATUS.

*Electrolytic Apparatus.* Max Haas, Ane, Germany. Patent No. 718,249, January 13, 1903. Application filed August 6, 1901.

The apparatus is an improvement on the well-known Haas and Oettel apparatus for the production of bleaching solutions. It aims at overcoming the loss of current incident upon the use of bipolar electrodes, and arising from the fact that the electrolyte itself forms a connection between the various compartments of an apparatus. In the present construction long, narrow tubes of non-conducting material are provided, through which the electrolyte has to flow in order to pass from one compartment into the other or from the storage reservoir into the various compartments, and thence to the collecting vessel. The idea is to oppose so much resistance to the current by the long pipe connection that it will be so much greater than the resistance within the compartments that practically all the current will flow through the compartments, and the loss become so small that it practically does not come into consideration. The bipolar electrodes are made of carbon, as in the older form of the Haas and Oettel apparatus. Motion of the electrolyte is brought about by the ascending bubbles of hydrogen, in substantially the same manner as in the German patents by the above inventors.

*Deposition of Metals on Earthenware Articles.* G. W. Layhourn, Hoke-upon-Trent, England. Patent No. 716,559, December 23, 1902. Application filed June 17, 1902.

The invention relates to the deposition of metals or metallic coatings on domestic, ornamental, sanitary and other earthenware articles, and its chief object is to deposit the metals after the articles have been specially prepared and brought to a highly porous condition. It is claimed that the conductivity of the water in which the articles are steeped before they are placed in the electroplating bath, and which fills the pores, greatly assists the deposition of the metals.

### Storage Batteries.

*Storage Battery.* C. H. Clare, Quincy, Mass. Patent No. 717,351, December 30, 1902. Application filed March 1, 1902.

The invention relates to storage batteries in which the active material is held upon the face of the lead plates by separating plates of insulating material, and is intended to overcome the tendency of the active material to fall out from between the plates. For this purpose the inventor arranges so-called "units," groups of electrodes, held rigidly together by plates of insulating material, such as glass, gutta percha, etc., on the four sides and on the bottom. Such a unit consists, in the order named, of an insulating plate, a lead plate, a layer of active material, two porous earthenware plates with openings between them for the circulation of the electrolyte, another layer of active material, a lead plate, another layer of active material, two porous plates with openings as before, a layer of active material, a lead plate and finally another insulating plate. An insulating plate at each end and one on the bottom complete the "unit," which is rigidly bound together by two "suitable" binders, the nature of which is not given. The porous earthenware plates serve also the purpose of pressing the active material against the surface of the lead plates. The two outer lead plates are connected together to form one electrode, while the inner lead plate forms the other electrode.

*Secondary Battery.* I. Kitsee, Philadelphia, Pa. Patent No. 717,416, December 30, 1902. Application filed April 10, 1893.

Application for this patent was filed nearly ten years ago, and a whole host of patents have since been taken out in this country and abroad with the same object in view, namely, to prevent the buckling of the electrodes by providing for the expansion of the active material. The electrode in this construction consists of a rectangular frame of conducting material, presumably lead, in which is placed a band of conducting material bent into zig-zag form, so as to form spaces, which are to be filled with active material. Soft rubber bands are then placed around the electrode thus formed, and a perforated sheet of non-conducting material is placed on each side. In order to keep these sheets in position, a second series of rubber bands is placed around the whole. The active material is provided with holes to allow for the circulation of the electrolyte. The conducting band is bent in such a manner as to allow room for the expansion of the active material.

*Secondary Battery.* W. Morrison, Chicago, Ill. Patent No. 717,107, December 30, 1902. Application filed May 19, 1900.

The inventor says: "To form the red lead into a paste, it is usually mixed with dilute sulphuric acid. This produces a small quantity of sulphate of lead, and in drying the sulphate of lead slowly sets into the mass as it hardens. With this construction, however, when the charging is carried too far, the lead sulphate is changed to a peroxide of lead, the sulphuric acid is expelled and the bond is relaxed until the peroxide coating powders and crumbles away. The object of the present invention is to overcome this difficulty, and this I have discovered may be accomplished by using hydrofluoric acid, by mixing it with the lead paste forming the active material. Hydrofluoric acid being strongly electropositive, it will unite with the sulphuric acid of the electrolyte to form a fluoride of lead, which resists the seductive effects of overcharging and perpetuates the bond of the paste, so as to prevent the latter from crumbling."

*Secondary Battery.* W. Morrison, Chicago, Ill. Patent No. 717,108, December 30, 1902. Application filed August 5, 1901.

In this patent the inventor states that the same result as

described above may be obtained by using fluorine or hydrofluoric acid or fluoride of lead or ammonia, or other compounds of lead, to be mixed with the electrolytic solution of the battery.

*Process of Preparing Storage Battery Plates.* R. C. Browne and F. Balch, Salem, Mass. Patent No. 710,603, December 23, 1902. Application filed April 21, 1902.

The inventors claim to have discovered a new process for preparing storage-battery plates prior to their formation. The following procedure, as described by them, is stated to have given the most satisfactory results, though they do not confine themselves to the exact proportions or temperatures, which may be varied to some extent: "To 30 ounces of sulphuric acid, at a temperature of 20° F., preferably contained in an open vessel or beaker, we add 17 ounces of potassium nitrate, and allow the temperature of the mixture to fall to 185° F. We then add 15 ounces of water and stir in 1½ ounces of ammonium sulphate, and when red fumes are given off we add 74 ounces more of water and allow the solution to cool to 70° F., at which temperature it is maintained while the plates are being treated. In our experience plates of lead immersed in the above-described solution and allowed to remain but three hours, while the temperature is maintained at 70° F., become heavily incrusted with scale in many superimposed layers, clinging together and of a porous nature, with a distinct grain . . . When the incrustation or coating of lead has been perfected in the solution, the plates are ready for forming by electrolysis." The inventors state that, as nearly as they have been able to ascertain, the scale is a lead sulphate, but they are led to believe by certain characteristics of it that a metallic salt is combined with the sulphate of lead, which hardens the latter and renders it more adherent.

*Storage Battery and Method of Preparing Electrodes Therefor.* L. Paget, New York City. Patent No. 717,610, January 6, 1903. Application filed January 10, 1900.

The specification describes a new form of electrode, made up of successive layers of spongy lead compressed to the density of sheet lead, 11.4 or thereabouts. Direct pressure—that is, the pressure of a press as distinguished from that of rolls—is necessary, and a pressure of from 2 to 3 tons is sufficient. The specific gravity of the compressed plates must not fall below ten, which involves loss of durability. If the specific gravity is less than about nine and one-half, the plates will be entirely unsuitable. An important feature of the invention is that the plates are built up of successive thin films, each not more than about two-hundredths of an inch in thickness. The spongy lead is applied on opposite sides of the element for successive compressions, with the result that the density of the layers will increase from the surface inward, and the plate will thus resemble a Planté plate. The thickness of the finished electrodes is stated to be about a quarter of an inch.

*Storage-Battery Electrode.* L. Paget, New York City. Patent No. 717,609, January 6, 1903. Application filed January 10, 1900.

This specification claims the electrode formed by the process outlined in the preceding patent of the same inventor.

*Method of Preparing Storage Battery Electrodes.* L. Paget, New York City. Patent No. 717,608, January 6, 1903. Application filed October 19, 1899.

*Electrode for Storage Batteries.* L. Paget, New York City. Patent No. 717,607, January 6, 1903. Application filed September 8, 1899.

These two inventions relate to a new form of storage-battery electrode and the process of preparing it. The construction of the electrode is illustrated in the accompany Fig. 2. It is formed of a series of small plates A, connected by lugs C to a common conductor B. Each of the small plates consists of a thin sheet, formed by compressing precipitated lead, and is provided with vertical corrugations. An elastic frame D of vulcanized rubber incloses the plates on the bottom and the sides. This construction permits the plates to expand and contract transversely to the corrugations during the process of charging and discharging. Each of the plates A is preferably not over an inch in width, and the thickness of them—that is, the depth of the corrugations and of the frame D—is from a quarter to a third of an inch. The sheets of lead, corrugated to form the plates, are preferably not more than one-half to one millimeter in thickness.

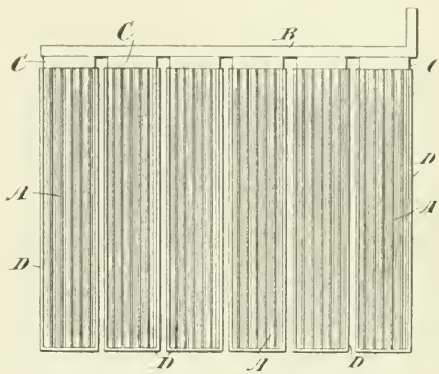

FIG. 2.—STORAGE BATTERY ELECTRODE.

*Electrical Storage Battery.* H. K. P. Barham, Portsmouth, England. Patent No. 718,045, January 6, 1903. Application filed December 2, 1901.

The battery is constructed out of a number of strips of sheet lead, arranged one above the other. Each strip is formed like a tray in its middle portion, with folded extensions at both ends. Between all the contiguous surfaces of the folding extensions and the trays are interposed sheets of absorbent or porous material, such as blotting paper, unsized paper, asbestos, etc. The absorbent sheets are saturated with an electrolyte, preferably dilute sulphuric acid.

*Secondary Battery.* J. W. Madigin, Toronto, Canada. Patent No. 718,489, January 13, 1903. Application filed February 5, 1902.

This battery, as shown by Fig. 3 in cross section, consists of a glass or rubber cell A, in which are arranged four electrodes B, B, B and C. The electrodes are separated from each other by rectangular plates or sheets F of fiber, cellulose or wood fiber, which is chemically treated with a neutral salt. The separating plates are porous, and consequently the electrolyte,

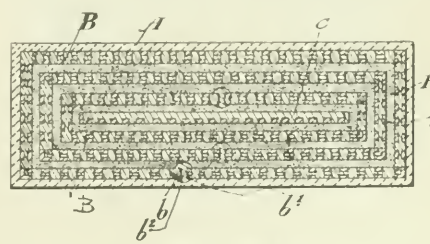

FIG. 3.—STORAGE BATTERY.

by capillary attraction, is drawn up from the bottom of the cell. The electrodes B are rectangular in form, and are constructed from a single sheet of metal folded at *b* and having its free ends at *b'*. The folded end *b* and the free ends *b'* are burnt together into the groove *br*. In this way a double plate is formed, leaving a space between, which is filled with active material. The plates are perforated in order to insure circula-

tion of the electrolyte. The inner plate C is formed with horizontal corrugations, and the space between the corrugations is filled with active material.

*Electric Battery.* M. R. Hutchinson, Upper Montclair, N. J. Patent No. 718,205, January 13, 1903. Application filed April 8, 1902.

This invention relates to electric batteries, both primary and secondary, and especially to the "dry" or "semi-dry" class. The inventor states that, as such cells generally contain a free space for the electrolyte at the top, it has been found in practice, when they are replenished, that the generated gases force the liquid out of the vent hole, which is very objectionable, especially if the cell is carried upon the person. In order to overcome this, he arranges the space for the electrolyte at the bottom or at the side of the cell, providing them with a liquid-tight plug, through which liquid can be poured into the cell after turning it upside down. When filled, the plugs are replaced and the cell turned right side up. The porous material interposed between the electrodes reaches down into the reservoir for the electrolyte, and by capillary attraction draws the liquid up.

*Battery Installation.* S. Lake, Bridgeport, Conn. Patent No. 716,844, December 23, 1902. Application filed and divided June 23, 1902.

"The present invention has for its object to prevent the escape from the storage-battery compartment of a submarine boat into the living quarters of the fumes or gases commonly set free from the battery fluid in the charging of batteries, and also to maintain the atmospheric pressure in such compartment substantially uniform and at a pre-determined tension, in order to prevent the rising of such pressure above a dangerous limit." Mechanical arrangements for accomplishing these objects are described in detail in the specification.

### Galvanic Cells.

*Electric Battery.* H. Halsey, New York City. Patent No. 717,394, December 30, 1902. Application filed April 18, 1902.

"This invention," says the inventor, "relates to that class of primary batteries invented by me in which one or both elements, wholly submerged, are revolved during the operation of the battery. . . . I employ in a battery a movable element and means for moving said element at any desirable rate of speed, and, inasmuch as the output of the battery will vary proportionately to the difference in speed between the element and the electrolyte, the output of the battery may be varied by varying the speed of the element. To maintain the constancy of the output, I provide means for keeping the surfaces of the elements clean." The cell shows a movable and a stationary electrode, the movable electrode being rotated by an electric motor run by current furnished by the cell itself. The revolving electrode carries brushes which rub against the surface of the stationary electrode for the purpose of keeping it clean and preventing polarization. Provision is also made for introducing depolarizing agents, such as bichromate of potassium. The mode of operation is described as follows: "The initial output of the battery is always sufficient to start the motor, and thus revolve the movable element. If the element remains stationary, the output of the battery will be first at its maximum, but as polarization increases the output will proportionately decrease; but, as the initial current from the battery starts the revolution of the element or electrolyte, the output of the battery will remain at maximum if the speed of the element or electrolyte be also maintained at its maximum." The idea of having to buy a motor with every galvanic cell is certainly a novel one, but it is doubtful whether it will find much favor with the general public.

*Electric Battery.* H. Halsey, New York City. Patent No. 717,395, December 30, 1902. Application filed April 18, 1902.

This invention covers substantially the same ground as the preceding, showing only a different mechanical arrangement for effecting depolarization of the electrodes. The motor for driving the movable electrode is again very much in evidence.

*Battery.* Louis Begeman, Cedar Falls, Iowa. Patent No. 718,076, January 13, 1903. Application filed January 7, 1902.

The construction is intended to be an improvement on the Lalande type of battery, in which the positive pole is formed of any suitable metal surrounded or covered by oxide of copper, which acts as depolarizing agent, the negative pole by zinc and caustic soda or potash used as electrolyte. The containing vessel, of tin, copper or iron, is corrugated, and the depolarizing agent, copper oxide, is supported in these corrugations. In order to keep the copper oxide in place, the vessel is lined with wire gauze, which in turn is covered by a shield of muslin or similar material to guard against any particles of the oxide falling through. This material is again supported by inner lining of wire gauze or netting, preferably of elastic metal. The zinc electrode is formed in the shape of a hollow cylinder.

*Electric Battery.* Georges Rosset, Paris, France. Patent No. 716,762, December 23, 1902. Application filed February 20, 1901.

The inventor proposes a new depolarizing agent, namely, the cuprates of the alkalies, and especially the cuprate of ammonia. The depolarizing agent may be obtained by introducing concentrated ammonia solution or ammonia gas into a concentrated solution of sulphate of copper and re-dissolving the precipitate in an excess of ammonia. The same procedure may be followed in order to produce the cuprates of potassium or sodium, only the excess of alkali intended to re-dissolve the precipitate is added in the presence of an organic substance, such as glycerine or tartaric acid. In order to avoid diffusion of the depolarizing agent, the inventor makes use of a porous vessel, in the pores of which he deposits a membrane of ferrocyanide of copper by substantially the same procedure as is familiar from the description of Pfeffer's osmotic experiments. A plate of carbon, forming the positive electrode, is placed in the porous vessel, the vessel filled with a concentrated solution of cuprate of ammonia and placed into an outer vessel containing a concentrated solution of sal-ammonia and a zinc rod as negative electrode. The action of the depolarizer is explained as follows: "Polarizing hydrogen appears at the carbon electrode, and reduces the cuprate solution to cuprite, but stops at this stage, because the reduction of cuprate to cuprite requires less work than the reduction of cuprite to metallic copper. The diffusion currents, aided by the lightness of the freed ammonia, bring this cuprite to the surface of the cell, where the oxygen of the atmosphere converts it back into cuprate, which, being denser, sinks back. During the operation the depolarizing agent consists of a mixture of cuprate, cuprite, deposited copper sometimes, and dissolved free ammonia; and this mixture, by self-regeneration, due to oxidation in the atmosphere, yields finally cuprate of ammonia."

*Electric-Battery Compound.* G. Bastedo, Brooklyn, N. Y.

This compound is intended for use in forming lead peroxide on the positive pole electrode in a lead and zinc battery, and consists of dilute sulphuric acid, 15 pounds; nitric acid, 50 grams; bisulphate of mercury, 1 ounce. The nitric acid and bisulphate of mercury are first thoroughly mixed, then the dilute sulphuric acid is added, and the whole thoroughly mixed again, when the compound is ready for use.

*Diaphragm for Batteries.* F. A. Decker and W. P. Divine, Philadelphia, Pa. Patent No. 717,549, January 6, 1903. Application filed April 9, 1902.

The diaphragm is made of clay, molded and baked, with reinforcing ribs and raised edges. The inventors claim to have found that the efficiency is greatly increased and the resistance greatly reduced by molding and baking the diaphragms of greater thickness than required, and then reducing the surfaces, with the exception of the reinforced portions, by

grinding or sand-blasting until a thin body of porous character is produced. Carbon diaphragms may be substituted for those of clay.

## MISCELLANEOUS.

*Process of Coating Phonograph Records.* T. A. Edison, Llewellyn Park, N. J. Patent No. 713,863, November 18, 1902. Application filed June 16, 1900.

In this specification T. A. Edison discloses a new method for coating phonograph records. Formerly he accomplished this object by causing the formation of an electric arc between two bodies of the metal of which the deposit was to be made

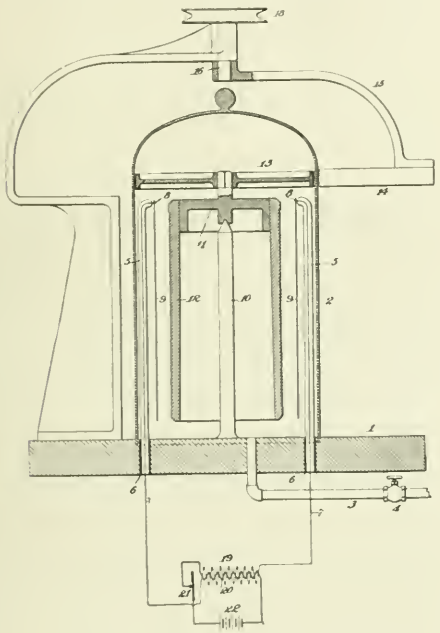

FIG. 4.—PHONOGRAPH RECORD APPARATUS.

in a vacuum, but it has been discovered that the rapidity of the process is increased and the disadvantages, such as injuring the delicate material by the heat of the arc, are avoided by the use of a silent discharge of electricity at high tension. Such a silent discharge may be produced from an induction coil of large capacity, or from a Helmholtz induction machine. The creation of a silent, or practically silent, discharge between two electrodes results in the vaporization of the metal, and the metallic vapors are carried directly toward and upon the record to be coated. The precipitation takes place most uniformly when the record is rotated, and, as the proper vaporization of the metal is only carried on in the presence of a high vacuum, the rotation is accomplished by a magnet outside the vacuum chamber. Fig. 4 illustrates the apparatus. A vacuum chamber 2 rests upon a base 1, and an exhaust pipe 3, to which an air pump or Sprengel pump can be attached, leads to the interior of the jar; 5, 5 are two supporting arms, preferably of glass, insulated from the base by hard rubber rings 6, into each of which a conductor 7 is introduced, with a hook 8 at its upper end. From each hook is suspended a strip or foil 9 of the metal, preferably gold, with which the record is to be coated, which strips serve as electrodes. A standard 10 mounted between the electrodes carries a rotating head 11, in which is supported a phonograph record 12. An iron or steel armature 13 is adapted to be rotated by a magnet 14, supported by arm 15 from shaft 16, carried by bracket 17 and rotated by pulley 18. In operation, the conductors 7, 7 are connected with the secondary of a large induction coil 19; the record is rotated, and the metal vaporized by the discharge is deposited upon it in an infinitesimally thin film. After that the cylinder is removed to a plating bath, where it receives a heavier deposit; and then the original record is removed, either by melting it out or by shrinking it from the deposited metal, leaving an absolutely accurate matrix of the original record.

*Apparatus for Purifying Water.* H. M. Livor, New York City. Patent No. 718,485, January 13, 1903. Application filed March 7, 1902.

The apparatus is shown in the accompanying illustration, Fig. 5, in which A represents a containing vessel for the purified water, made preferably of insulating material. F is a vessel containing an interior filtering chamber F', the lower end of which is provided with a cylindrical wire gauze or netting G, filled with sand M. O is a connection between filter and supply chamber. The electrolysis of the water takes place in vessel B, which is constructed of insulating material, and has at its bottom a flange, with which it fits into vessel A. A closely-fitting metallic ring E', made preferably of aluminium, constitutes one electrode. The other electrode, arranged concentric to the first, consists of an aluminium cylinder C. L, L are brackets on the inner surface of the electrode C, upon which rests an insulating disk H, supporting a strong spiral spring S, the upper end of which bears against a similar disk H' secured to the bottom of the metallic water-supply chamber E, which rests normally with its bottom on the cylindrical electrode C, thus making good electrical contact therewith; *b* and *b'* are binding posts connected with the respective electrodes. In operation, the water flows from chamber E through cock I and tube J into the annular space between the electrodes. There it is subjected to the action of the current and overflows through P and the tube H into the filtering vessel F, then upward through the wire gauze G and sand filter M through

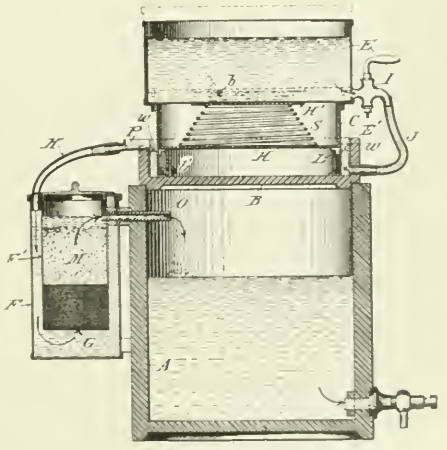

FIG. 5.—APPARATUS FOR PURIFYING WATER.

the pipe O into the container A. When the level of the water falls too low in vessel E, the spring S comes into action and lifts the vessel into the position shown in dotted lines, thus interrupting the contact between vessel E and the electrode C. The apparatus can be quickly disconnected, and the filter easily taken out and cleaned.

*Process of Electrolytically Preparing Metals and Alloys for Lithographic Purposes.* O. C. Strecker, Cologne, Germany. Patent No. 710,309, December 16, 1902. Application filed April 19, 1900.

The inventor claims: "The process for preparing metal

plate and alloys for lithographic printing, consisting in preparing the plate by preliminary grinding, rinsing, subjecting to an acidulated watery solution, washing and drying, fixing the negative upon the surface thus prepared, coating with gum arabic, treating with lithophane after the gum arabic has tried to dissolve the greasy substance, washing the plate with water to free it from the gum arabic, dusting with powdered colophane and rubbing this off, then submitting the plate as an electrode to electrolytic action in a solution of salts and gum arabic." The plate is used as anode in an electrolyte composed of a solution of 2.5 per cent. of fluoride of sodium. The density of the current is 0.5 to 0.9 ampères per square foot, and the action may last from two to five minutes. Zinc plates are preferred, on account of the cheapness of the material and the exceedingly good results obtained. An alternating current may also be used, in which case the electrolyte will be a solution of borax neutralized with boric acid 2 per cent. strong. By using this method, the current oxidizes the plate to ZnO, which is then treated with a weak solution of acid, preferably phosphoric acid. In special cases an electrolyte of a mixture of 3 ounces of ammonium silico fluoride, 3 ounces of ammonium nitrate and 3 ounces of gum arabic in $1^1/_2$ pints of water is employed.

## LORD KELVIN AND GEORGE WESTINGHOUSE.

At Claridge's Hotel, in London, on the night of January 9th, Mr. George Westinghouse entertained at dinner a large company of British railway managers, financiers and scientists. Two speeches were made of unique interest. One of these was by Lord Kelvin, the other by the host of the occasion. Although no electrochemical subjects were touched upon, these speeches will certainly be of particular interest to our readers, as they are characteristic of the speakers and as the subject of specific American methods in engineering discussed by Mr. Westinghouse should be of general interest.

Lord Kelvin said:

"At this dinner of friends I would like to express a common sentiment which all must feel, our appreciation of the qualities of our charming and beloved host, Mr. Westinghouse. I am sure that Mr. Westinghouse's coming to England reminds us all of the advantages that England has derived from his genius and perseverance and grand skill in bringing out for the public good so many of the results of science and inventiveness. There are many railway men present at this table and many passengers by railways, which means that every inhabitant of our country is represented here. When people belonging to these two classes—the railway men and the traveling public of Great Britain—are gathered together, as now, we can scarcely see Mr. Westinghouse without feeling how much we owe to him for the Westinghouse brake.

"But Mr. Westinghouse has not stopped with his brake. He has gone on, and on and on in America, flashing over again on this side of the Atlantic and bringing his energies here. The present development of the electric industry in the United Kingdom owes its growth largely to him.

"'Largely' is a small word to express how much we owe to him. I do not wish to enter into any comparisons of superlatives, but I do not think any man in the world of engineering could be named to whom more is due than to Mr. Westinghouse for his work in electric engineering.

"Other things besides mechanical engineering and electrical engineering we owe to Mr. Westinghouse. We owe to him the bringing to England, and causing to be appreciated in England, American methods—American methods in a certain way which I may refer to without invidious comparison. American methods of industry and resolution and determination, which are also English methods, because they have been inherited from England. Here it comes back to us with compound interest in the shape of Mr. Westinghouse, and I am sure that we all feel that we are largely indebted to him for what he has done for us, what he is doing for us and, in advance, for what he is planning to do for us in the future.

"We appreciate all this, and we appreciate him as a kind friend, a genial host and entertainer. I ask you to join me in drinking the health of Mr. George Westinghouse."

The toast having been honored with enthusiasm, Mr. Westinghouse rose to respond. He said:

"I wish to thank our distinguished scientific friend, Lord Kelvin, for the complimentary language he has used about me. And I would like to say to all you railway men here present that my life has been very much associated with your calling. I invented the brake of which Lord Kelvin has spoken when I was scarcely twenty-one years old, and thus became acquainted with railway men when the railway industry was rather a poor one compared with what it is to-day. Since then I have closely followed railway operations, becoming acquainted with almost everything that is being done in them; and it is particularly my friendship with railway men which has prompted me to go forward in my work with an interest and keenness that probably would not have resulted from ordinary commercial motives.

"Lord Kelvin has been good enough to refer to my coming to this country. I came here thirty years ago, and for ten years or so I was here about half the time. At that time it was very difficult to get any new thing done in England. I often wanted to sit down and cry, because I could not get anyone to believe in anything. I wanted in those early days to try an iron brake shoe, because, on account of rapid wear, we couldn't keep the wooden one adjusted. I had to beg and beg to be permitted to put a set of metal brake shoes on one tender on the Caledonian Railway. Finally I succeeded. You all know that nowadays all the railway shoes or blocks are made of cast iron or other metal, and are used upon all the wheels of the train.

"Lord Kelvin has alluded to 'American methods.' May I say that one of your English difficulties is inherited I think in an old-world, highly-developed country. After a man (or a nation) has worked prosperously for a long time, he opposes improvement or suggestion, thinking: 'What I have is good enough. I won't try a new thing.' In America, however, the necessities have produced different results. Lord Kelvin speaks of England having sent many men to America. It has also sent to us many ideas. If you take up the American patent records and follow the cases in litigation especially, you will find that among the references cited many are of English origin, some of them containing ideas so complete that wonder is that the inventions disclosed were not established fully and completely in your own land. These records seem to show that Americans and Englishmen have invented the same thing many times.

"In America, however, we have always been short-handed with regard to labor. We have been obliged to find methods whereby one man may accomplish the work of two or three men as compared with your practice here. We have had the best men from Europe—Englishmen, Germans, French, everybody, skilled men, highly-trained men, as well as laboring men. We have combined their experience with our own, coupled it with our necessities, and have thus accomplished results unattainable in a country like this, where you have more labor than you can well keep employed.

"As an illustration of what has been accomplished by the use of electricity in a great industry, I may cite the Homestead Mills of the Carengie Co. Mr. Schwab, whose name is well known to you, is a genius in his way, particularly in the management of men; he is a master in organizing and directing men. Mr. Carnegie believed in him, and if Mr. Schwab made a suggestion in regard to the use of new appliances, even if it involved the tearing down of an old mill and putting up a new one, the new one was ordered. What Mr. Schwab thought should be done was done. As a result of such progressiveness we may see the splendid mills at Homestead, where they pro-

duce, with about 4,000 men, three times as much steel as the Krupp works produce with 15,000 men. The results are simply wonderful. You can start there to-day, in a building containing steel-melting furnaces, and you will there see three men mounted on a car with the charging apparatus, which is moved and operated by electricity. With a few movements of this ingenious contrivance three men charge 20 furnaces, which, prior to the use of electricity, would have required the labor of over 200 men.

"You may go into the yard of the Homestead Mills, where they pile the metal in stock. This yard is covered by a system of overhead cranes, and the result is that not only here, but in the mill and in every other place, you may see great weights lifted and many undertakings going on without a single man exerting himself a bit working not half as hard as I am working now.

"I took some English friends to Homestead. Mr. Schwab, after guiding us through several departments, said: 'I will now show you where we turn out 750 tons of plate girders per day.' The mill was in the shape of an L. We went into the short end of the L, where the furnaces were fed by natural gas, of course, requiring no stokers. The end at which we entered had a rather low roof, and there was in a sight a contrivance like a battering ram in front of the furnaces. Two workmen were sitting down eating their dinners near by; no one else was present. I thought: 'Mr. Schwab has made a mistake; he has asked us to see a mill that is not in operation.' But we went through the mill, which was about 200 feet long. Suddenly we heard a rattle, and then saw a truck approaching loaded with a big ingot. No one touched the truck or the ingot. The load came to a platform; the crane overhead dropped a pair of tongs and quickly put the ingot on the roller table, and as it moved along to the great rolls it was automatically kept in place. The adjusting screws of the rolls were turned by little electric motors, and not a man in that house did a bit of work. It was just as easy as what you are doing now—looking on. We went back to the furnaces. There was a fifteen-year-old boy seated in a little place called the 'pulpit.' He was able, merely by the movement of levers, to open at will any of the furnace doors and move the car along. And we saw this car come in front of a furnace and the charging machine approach and take out of the open furnace a hot ingot, which was dropped on the car and moved off to its work. There was this boy doing absolutely no hard work, and his mill was turning out 750 tons of steel plate each day. My English friends said: 'England has no chance in competition with such methods.'

"Now, all this sort of thing came about in America because of our necessities. We hadn't men enough to do our work. There was a premium in favor of those who could invent machines to work, and thus supply the deficiency.

"At the Carnegie Mills we went to see three blast furnaces. They were making 1,800 tons of pig iron in twenty-four hours. We saw only two or three men on a truck, which was moved automatically. These men were letting the ore run from shoots and mixing it in the required quantity; and when they had filled a truck it was carried up and its contents dumped into a furnace, whence it returned for another load. They were running the metal into an immense receptacle, into which the metal from all three furnaces was mixed. From this place the metal was taken as required, put into a special tank, mounted on a car and taken to Homestead, two or three miles away, to be poured into the furnaces. One heating only was required.

"I refer to all this simply to illustrate the immense advantages we have had in America, and the kind of experience I have been able to bring to this country, and to which Lord Kelvin so generously alluded, and which I hope will be not only useful and profitable, but will establish for the company I represent a name and a position which you will all regard as most satisfactory.

"I want to thank you very sincerely for the kind expressions with which you have greeted me, and especially for your acceptance of my invitation to inspect this evening a couple of inventions, one of which, the Hewitt mercury vapor lamp, is a complete and accomplished thing. The rays of this light are not very pleasant as yet, but the light is likely, however, to be of great value. The other invention, the Hewitt static converter, is quite new, and its object is to convert alternating currents into direct current at so low a cost in comparison with the sums which have heretofore been expended for equivalent results that it is likely, when fully perfected, to cause an immense stimulus in regard to the use of electricity in all parts of England, and particularly in the agricultural parts of the country for farm work and for moving all kinds of vehicles.

"I have taken advantage of these inventions to invite you to see them as my guests, and I thank you for having honored me with your presence to-night."

# SYNOPSIS OF ARTICLES IN OTHER JOURNALS.

*I. Summary of Articles on Electrochemistry and Allied Subjects Appearing in American and Foreign Periodicals.*

By CARL HERING.

## INDUSTRIAL ELECTROCHEMISTRY.

*Nickel Industry.*—What seems to be a good statistical review of this industry in Canada is given in the January 9th number of London *Engineering*. The Canadian and Orford Copper Companies, which have been consolidated with the International Nickel Co., are still the most important producing concerns in the Dominion. The principal works of the Canadian Co. are at Copper Cliff, which covers 10,000 acres of the best mineral land in Ontario, and last year a feature of the company's business was the opening of an immense deposit of nickelliferous pyrrhotite and copper pyrites at the Creighton Mine. Operations were commenced in July, 1900, and now the surface plant is producing from 500 to 600 tons of ore daily for shipment to the roasting yards at Copper Cliff. There have recently been completed extensive smelting works, three-quarters of a mile southwest of Copper Cliff, and these have been utilized for the re-treating of low-grade mattes produced at the Copper Cliff smelters, with the result that their metal contents have been raised from 30 to about 70 per cent. This result is effected by crushing, grinding, calcining and re-smelting the mattes, thus getting rid of a great deal of the rock matter, iron and sulphur and producing an article much nearer the point of refinement and separation of the metals. For the final separation of the copper and nickel, this material is sent to New Jersey. The process includes a series of smeltings with various alkalies, followed by an electrolytic treatment for the purpose of producing pure nickel. One of the companies outside of the combination is the Mond Nickel Co., whose mines at Victoria have been very considerably developed during the past year, the Bessemer process having been put down for turning out the matte. The product is a high-grade article, carrying about 80 per cent. metallic contents in equal proportions of nickel and copper, the iron in the one being at the same time entirely eliminated. This matte is brought to England, where it is refined at the Swansen works by Mond's own process. During the past ten years 1,306,722 tons of nickel,

copper and copper ore, producing 26,606 tons of metallic nickel and 28,070 tons of metallic copper, have been produced in Ontario, the value of the nickel being over $20,000,000 and the value of the copper nearly $6,250,000. The rate of development has been very much greater during the last five years than in the first half of the decade. The most striking development has been in the production of high-grade matte, which in 1897 only amounted to 328 tons, whereas last year it was 15,540 tons.

*Electrometallurgy.*—In the continuation of his series on electrometallurgical problems in the Lond. *Elec. Rev.*, January 9th, Beadle discusses the manufacture of aluminium, magnesium and sodium.

*Separation of Metals from their Ores.* It has been the cause of some surprise that so little attention seems to have been given to the possible application of electrostatic forces to the separation of metals, such as gold, which often exists in very fine particles. The explanation is probably that the forces are too small. It appears, however, that Negreano has had some success in this direction, as he describes such a method in *Comptes Rendus*, December 15th, an abstract of which is in the Lond. *Electrician*. His method is based on the following experiment: A disk is cut out from the center of a metallic plate, and the plate and disk are connected with the two poles of a Wimshurst machine. If now a powdered mixture of sulphur and red lead is blown upon the metallic surface through a wooden sieve, the sulphur will be deposited upon the disk and the minium upon the other plate, or *vice versa*. This is due to the frictional electrification of the two powders in passing through the wooden sieve. He then mixed pulverized silica rock with malachite, iron oxide and copper oxide, and found that the metallic particles could be separated from the silica in the same way. In the case of a quartz rock containing limonite, the separation was easily brought about; also in separating pyrites from a matrix of lignite. The author proposes to employ this method for the separation of gold from gold dust.

*Electrolytic Rectifier.*—In the storage of electrical energy, mechanical methods fail and electrochemical methods must be resorted to in the storage battery. It seems that, similarly, though to a less degree, electrochemical methods may succeed in partly replacing mechanical methods in the rectification of alternating currents and in making cheap condensers. While it does not seem likely at present that the electrolytic rectifier will supersede the present converter or the motor generator, yet there is quite a field of its own, especially for converting small quantities, when moving machinery would be objectionable or expensive. Much has been written about the aluminium rectifier, and it seems that the original experimenters have abandoned it. It is therefore of interest to see that it is now being put on the market in France as a commercial apparatus in a new form, devised by Nodon. The London *Electrician*, January 23d, gives an illustrated description, from which the following is taken: Fig. 1 shows the construction of the electrolytic "valve," as it is called by the inventor.

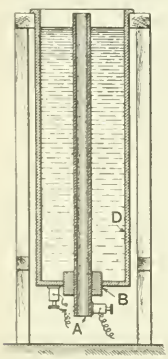

FIG. 1.—RECTIFIER.

It is extremely simple in design, and consists merely of a hollow cylinder A of a zinc and aluminium alloy immersed in a solution of ammonium phosphate. A containing vessel D of iron forms the other electrode, from which the cylinder A is insulated by the rubber plug B. On starting the valve, it merely acts as a liquid resistance, and does not choke back one-half of each alternation. This, however, only lasts for a very brief time, and after a few minutes a film commences to form on the surface of the aluminium electrode. It is this film which permits current to pass in one direction only. In order to utilize both half waves of the alternating current, the Graetz arrangement is used, as shown in Fig. 2. When used in connection with polyphase systems, the apparatus becomes rather more complicated, and it is necessary to use a number of cells equal to twice the number of wires used in distribution. For instance, six would be required for a three-wire, three-phase system. Each cell may be used for rectifying a current having from 50 to 140 volts, but when the voltage exceeds the latter figure two or more cells must be connected in series, allowing 140 volts as a maximum for each cell. Regulation in connection with these valves, having a capacity of more than 4 kilowatts, may be effected either by a choking coil on the alternating current side of the apapratus or by the adjustment of insulating sleeves, which may be made to cover or expose more or less of the aluminium-zinc cylinders. The efficiency is claimed to remain practically constant for all loads, and to seldom fall below 75 per cent. The loss consists in a reduction of 10 to 12 per cent. of the e. m. f., and of a leakage of alternating current within the rectifier corresponding to from 10 to 12 per cent. of the energy utilized. This energy is dissipated in heat which is liberated within the cell, and causes the temperature of the latter to rise to almost 50° C., after which radiation from the metallic casing prevents a further excessive rise. The frequency, within ordinary limits, appears to have no effect on the efficiency of the apparatus. The apparatus is put on the market in groups of four cells, connected as in Fig. 2. These four cells are put together in a frame, and below them a fan is provided; the aluminium cylinders being made hollow, a strong cooling draught passing through them. The current density is made at about 5 ampères per square decimeter of active surface of aluminium. Nodon has also designed an electrolytic condenser on the same principle as his rectifier, which possesses a considerable capacity for its size, for use in starting alternating-current motors and for similar purposes. The rectifier is now being put on the market in sets of cells large enough to deal with 10 kilowatts at the maximum voltage of 140. The price of a complete set of four cells, having a capacity of 5 kilowatts for a single-phase circuit, is $150. The writer of that article remarks that "this price would appear to be almost prohibitive in the case of motors connected to single-phase circuits, but, as the construction of the valve is simple, it may safely be inferred that the selling price would be considerably reduced if there should be a real demand for this apparatus."

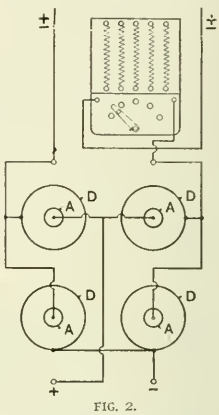

FIG. 2.
ARRANGEMENT OF FOUR CELLS.

An account of some tests made with this apparatus is given by Hospitalier in *L'Ind. Elec.*, December 10th. The tests were made at the School of Industrial Physics and Chemistry of the City of Paris. Four cells were used, and were arranged like a Wheatston bridge, as first used by Graetz for this purpose. One of the diagonal circuits is supplied with the alternating current to be rectified, while the other contains the apparatus in which the rectified current is to be used. As is well known, the former arms each contain one of the "valves." This arrangement enables one to utilize both half curves of the alternating current in the same circuit. The frequency of the alternating current in the experiments was 42, and an electrolytic valve of the 5-ampère type was used. The rectified cur-

rent was used to charge a storage battery of 42 cells in series. The wave forms of the currents and e. m. f.'s were determined by means of the ondograph, and are reproduced in diagram. The efficiency of the rectifier was found to be about 70 per cent., and the wasted energy appears in the form of heat, so that the temperature of the electrolyte increases. This is said to cause no other inconvenience than the evaporation of the liquid, requiring that water must be filled in at intervals. The electrolytic rectifier behaves like a condenser, the current being about one-quarter period in advance of the e. m. f. The deformations of the current wave are the same as are obtained with a condenser, and are due to the presence of higher harmonics.

## THEORETICAL AND EXPERIMENTAL.

*Dissociation of Electrolytes.* The *Zeit f. Elektrochemie*, December 25th, contains a theoretical article by LIEBENOW, in which he discusses the reasons for the discrepancies in Ostwald's well-known formula for the dependency of the electrolytic conductivity of a solution upon its concentration, which formula does not always accord with the facts. As is well known, this formula is in very good agreement with the results obtained for a very large number of organic acids which are relatively only slightly dissociated. For the ordinary inorganic acids and salts which are strongly dissociated, the formula does not agree at all with the facts. Ostwald deduced his formula directly as a consequence of the law of chemical mass action. He considers that state of a solution in which $y$ gram molecules of a salt, say potassium chloride, are dissolved in one liter of water, and in which $x$ of these $y$ gram molecules are dissociated into $x$ positive potassium ions and $x$ negative chlorine ions. There is a constant tendency of the dissociated ions to combine again and to form neutral molecules, and at the same time there exists also constantly the opposite tendency of the neutral salt molecules to dissociate into ions. There is equilibrium if both tendencies balance, *i. e.*, if the number of neutral salt molecules dissociated in a certain time into ions is equal to the number of new salt molecules formed from ions. According to the law of chemical mass action, the first number is $b(y - x)$, in which $b$ is a constant and the second is $ax^2$, in which $a$ is also a constant, hence there is equilibrium if $ax^2 = b(y - x)$. This is the basis of Ostwald's formula. The present author discusses this equation from the point of view of the theory that heat is due to irregular oscillations and movements of atoms. The left-hand part of the above equation then becomes clear. A large number of electrically-charged ions are in rapid movement in the electrolyte. If by chance a positive ion comes into a favorable position with respect to a negative one, they will unite to form a neutral molecule. It is clear that the number of such favorable positions must be proportional to the product of the concentrations of both ions, hence the term $ax^2$ in the above equation. The right-hand part of the equation is not as self-evident; $y - x$ is the number of neutral molecules, and if the number of such molecules which are dissociated into ions in a certain time is to be directly proportional to the number of existing molecules, it would be necessary to assume that such a dissociation is not due to a collision of a salt molecule with an ion, nor of a salt molecule with a salt molecule, but of a salt molecule with molecules of water. In order to explain this, he refers to the Nernst-Thompson rule, stating that there is in general a parallelism between the degree of dissociation and the dielectric constant of the solvent. This rule is easily explained if one assumes that the neutral salt molecules are not really electrically neutral, but that in a KCl molecule, for instance, the K atom has its positive charge and the Cl its negative charge. But the two charged atoms cling together and are not separate ions, but form a molecule which is electrically polarized. According to the ordinary laws of electrostatics, the greater the dielectric constant of the solvent the smaller is the force of attraction between both atoms, *i. e.*, the more is such a polarized salt molecule liable to be ionized if a force to that effect is acting from the outside. Now, such a force would exist if a charged ion comes into the proximity of a polarized salt molecule. The first action of the ion upon the molecule will be to exert a torsion of the molecule so that the ion comes to lie in the continuation of the axis of the polarized molecule. The attracting force of the ion upon the oppositely charged atom of the polarized molecule is then a maximum, and a disruption of the molecule is liable to take place. This is the fundamental conception upon which the author bases his calculations. His final result is $\frac{m^2}{(1-m)v} = A - B\left(\frac{m}{v}\right)$, where A and B are constants, $v$ is the quantity of water in which one gram molecule of salt is dissolved and $m$ is the ratio of the molecular electrolytic conductivity to that for infinite dilution. Ostwald's final equation is a special case of the above, namely, if $B = 0$. As Ostwald's final formula contains only one empirical constant and the above two, it is to be expected that the latter can be made to agree better with the facts than the former. Indeed, the author shows that for potassium chloride the difference between the calculated and the measured values is always less than 1 per cent for a range of concentrations between 0.0001 and 3.

*Phase Rule.*—A long abstract is published in the *Zeit. f. Elektrochemie*, December 25th, illustrated by diagrams, of a lecture by VAN'T HOFF on Gibbs' phase rule, its application to different cases and on graphical methods for representing such chemical problems. He thinks that the very great, but mainly formal, value of the phase rule will never make it superfluous to treat problems of chemical equilibrium in accordance with molecular theories.

*Action of Halogens on Alkalies.*—A contribution to the theory of the action of halogens upon alkalies is given by FOERSTER and MUELLER in the *Zeit. f. Elektrochemie*, December 18th. If a zinc rod is placed in a copper sulphate solution, the reaction is $Zn + CuSO_4 = ZnSO_4 + Cu$. From the point of view of the electrolytic dissociation theory, this equation can be written $Zn + Cu^{\cdot\cdot} = Zn^{\cdot\cdot} + Cu$, where each dot represents a positive electric charge; so that the process may be expressed by stating that the zinc atoms take positive charges from the copper ions, so that the zinc atoms become ions and the copper ions become atoms (exactly the process in the Daniell cell). An analogous consideration may be applied to the action of halogens upon alkali. If this action would be exactly analogous to the above, the equation becomes $X_2 + 2KOH = 2KX + H_2O + O$, where X is a halogen. Or if we write the equations of the ions, it becomes $X_2 + 2OH' = 2X' + H_2O + O$, where the sign ' represents a negative electric charge. It is known, however, that only fluorine behaves in this way, while for the other halogens the process is more complicated. The authors show that the process of the action of any quantity of a halogen upon any quantity of an alkali consists in the formation of two conditions of equilibrium, which are represented by the following equations:

$$X_2 + OH' = X' + XOH$$
$$XOH + OH' = XO' + H_2O.$$

The authors calculate the numerical constants which determine these equilibria and apply their theory especially to the case of the action of chlorine upon an alkali.

*Spontaneous Deozonization.*—If partly ozonized oxygen is left to itself, the proportion of ozone decreases with the time. This phenomenon is known under the name of spontaneous deozonization, and may be due to a variety of causes. WARBURG points out in the *Ann d Phys*, November 12th, that since the amount of ozone at 200 degrees is a state of equilibrium is inappreciable such equilibrium can be attained at ordinary temperatures only by complete dissociation of the ozone. The factors bringing about this dissociation may be external, as for instance, a contact with foreign bodies or with the walls of the vessel; or they may be internal and due to the collision of two molecules of ozone or of a molecule of ozone with a molecule of oxygen. He formulates a mathematical

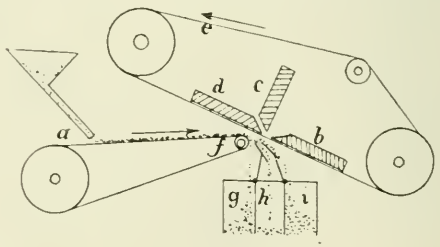
theory of the process, and finds by suitable experiments that the internal effects are almost entirely due to collisions between the gas molecules themselves. Heat increases this internal disintegration much more rapidly than it does the external process, and it becomes the chief agent at high temperatures. He finds that moisture makes no difference to the stability of ozone at 100 degrees. An abstract may be found in the Lond. Elec., January 9th.

## PRIMARY AND SECONDARY BATTERIES.

*Plates Made of Slabs of Active Material.*—The literature on storage batteries during the past month has been scant. About the only matter of interest is an article by Leimer, who seems to have given very much attention to the manufacture of accumulator plates made of a solid slab of material. Such plates are not new, as they were made and tested by the present writer nearly twenty years ago. The difficulty did not seem to lie so much in the making of such slabs, as there are various processes by which this can be successfully done; but it seems to lie more in making and maintaining a good contact between the slabs and the conductors or frame; also in the fragility of the slabs, as those of peroxide are very brittle and become soft in time, while those of spongy lead have at all times very little strength. This direction of development of storage-battery plates has always been a tempting one, although it does not seem to the writer to be a very promising one. However, Leimer's experiences may be of interest and use. The beginning of his description is given in the *Centralbl. f. Accum.*, January 1st. He claims that such plates have the advantage over those of the Planté and the Faure type, in that they have a very high capacity in a small volume and a relatively low weight, and that they are strong and light enough to be used for traction purposes; but they require very careful treatment during manufacture. Although the correct choice and use of the pasting material is of importance, yet the main point is the careful treatment of the plates themselves in all the phases of their manufacture. He has found phenole in aqueous solution to be suitable for a binding material; it forms a basic phenylate with lead oxides, while in alcoholic solutions it does not. For preparing the "solution," he mixed, in his first experiments, 1 part of the purest crystallized carbolic acid (98.8 per cent.) with 15 parts of distilled water. With this solution the minium and litharge are moistened so that they can be shaped by hand without giving off free liquid. For the positive plates, pure minium was used, but not every kind of minium is suitable. He cites a case where, out of ten different kinds, only one would answer. Sometimes a kind of minium is unsuitable, although the percentage of oxygen is high and there are no impurities. The pasting of this material into the frames must be done with great care; all places like corners must be well filled out. When the surface has been made smooth, but still has some holes or depressions, it will not do to fill them up with the mass, as it will always be found to scale off during the formation. In no case should more minium be moistened with the solution than can be used on the same day. The pasted plates should be perforated at once, and should be treated with great care before they are placed into the acid bath. To prevent the mass from sticking on the glass plates before the pasting, the frames are separated from the glass plate by a piece of wood paper. The pasted plates, after having been perforated, are placed with their surface upon a fresh piece of paper, and, with this upon a glass plate, the plates are thus placed above each other, the upper plate being also covered with paper and glass plate. In this condition the plates are left for at least twelve hours, after which they are brought into the drying oven, which is so designed that it is air-tight. During this period a pure, dry, hot stream of air passes through it, the temperature being adjustable. In the stove the plates are placed one above the other in two series, so that each plate touches the next one with the long side. The plates must be exactly perpendicular, and at a distance of at least 1 centimeter to accomplish a uniform drying process on both sides. They should stand, and not lie horizontally, while being dried. At the beginning of the drying, the temperature should not be more than 40 or 50 degrees; after twelve hours it is raised to about 120 or 150 degrees, and this temperature is kept constant for about thirty-six hours. The temperature is then decreased, and the oven is left to itself to cool. After twelve hours the plates, which then have about the temperature of the hand, are placed at once into the acid bath, which should have the same temperature. It is important that the plates should not be left in the ordinary atmospheric air, as he found that this had a bad effect upon them. When prepared by the process just described, they could not well be formed. It was found that the solution of carbolic acid, mentioned above, was too strong; therefore solutions more dilute than 1 ÷ 15 were tried, and finally he found that solutions of 2 to 3 per cent. were the best. Moreover, he found that the plates must remain in the acid bath only for a certain time, and that it is important to keep this at a definite density and temperature. The exact time during which the plates must be left in the acid bath depends upon the porosity and the thickness of the mass. He obtained the best results with thirty-six hours for each 2 millimeter thickness of mass; plates of 140 x 100 x 6 millimeters were therefore left in the acid bath for about one hundred hours. Care must be taken that the acid strength never decreases below 10 degrees Baumé, and when freshly prepared it should not be more than 12 degrees Baumé. If a basin of too small a volume is used, the acid strength decreases very rapidly to zero Baumé. Plates which were left even only a short time in too weak an acid did not stand the formation. In this part of his article he says nothing about the making or maintaining of the contacts.

## MISCELLANEOUS.

*Magnetic Separators.*—In the continuation of his long illustrated serial on the Dusseldorf Exhibition, in the *Zeit. f. Elektrochemie*, January 8th, Danneel discusses a number of metallurgical apparatus which were exhibited. Most of them are purely mechanical, but among them are some magnetic separators. The adjoining diagram shows the Wetherill separator. The finely-crushed ore falls upon a belt *f*, which is moving in the direction of the arrow around two rollers; *d, c, b* are three electromagnets, which form a strong magnetic field. Under the action of the magnetic field, the ore is separated into three parts; the strongly magnetic part drops into the box *i*, the non-magnetic part into the box *g* and that of medium



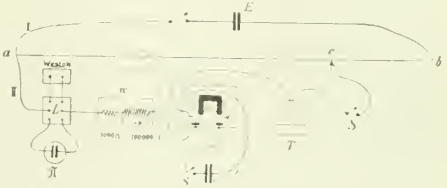
MAGNETIC SEPARATOR.

magnetism into the box *h*. The three boxes are separated from each other by two walls, which are so arranged that when the electromagnets are not excited all the ore drops into the box *g*. A ribbon *e* is provided, moving in the direction of the arrow, in order to prevent magnetic particles from sticking to the magnets. Another magnetic separator which is exhibited is designed by Heberle for a wet process. The particles of ore fall down through a rising stream of water, and are exposed at the same time to the action of a magnetic field. The chief advantage of this construction is said to be that the adhesion between the single particles of ore is so completely removed that the magnetic particles are absolutely free; that is, they are independent of the non-magnetic particles, and are thus enabled

to follow the magnetic attraction. In this way a satisfactory separation of fine powders becomes possible.

*Portable Capillary Electrometer.*—The capillary electrometer is of special interest to electrochemists, as it is especially adapted, in fact limited, to very low voltages; but it measures these with great precision. It is therefore convenient also for measuring the differences between two voltages, be they large or small, providing only that they are very nearly alike. In a recent (Brit.) Physical Society paper SMITH describes an instrument which is a modification of a form of capillary electrometer, consisting of two wide tubes joined by a cylindrical capillary tube, which may be horizontal or inclined. The apparatus contains mercury and sulphuric acid of about maximum conductivity, suitably distributed in the tubes. A spring key is commonly employed with such an instrument, and keeps the two platinum terminals at the same potential whenever the spring is not depressed; when depressed, the terminals are put in contact with the two points, the potentials of which are to be tested for equality. In the instrument shown by the author, the two wide tubes are sealed at the top to prevent evaporation of the sulphuric acid. The wide tubes are also joined near the top by another tube, which allows free motion of the liquids within the apparatus. With this arrangement, the instrument is made air tight, and can, if desired, be made free of air by exhausting the apparatus before sealing. The distribution of the mercury can be altered most easily by means of a third cross piece, which is provided with a tap. To prevent the platinum wires which form the electrodes from being wetted by the acid, if the apparatus should accidentally or during transit be laid on its side or turned upside down, the lower ends of the tubes may be slightly constricted above the ends of the platinum terminals. If the terminals consist of amalgamated platinum foil, the constriction is unnecessary. If a spring key is made of brass, the contacts frequently become unsatisfactory through surface tarnishing; and if, to avoid this, the bearing surfaces are made of platinum, the key may be subject to thermo-electric effects. Such a key cannot conveniently be fastened on the same stand as the rest of the instrument, for, unless the stand and the support on which it rests are very rigid, the pressure necessary to depress the spring produces sufficient movement of the meniscus during the act of depression to render the detection of minute changes of surface tension impossible. These difficulties are overcome by using a key consisting of a U tube closed at one end, communicating at the other with a pneumatic pressure-ball and containing mercury in the bend. Three platinum wires are fused into the tube, so that by squeezing the ball the same change of contacts is produced as by pressing the lever of an ordinary spring key. This form of key can be extended so that a slight pressure applied to the ball makes it work as an ordinary electrometer key, and greater pressure reverses the contacts between the terminals and the points under investigation. With such an arrangement, the sensitiveness of the instrument is doubled, and, by using a microscope magnifying 50 diameters, a P. D. of 1-10,000 volt can be detected without difficulty. The instrument, used as a surface tension galvanometer, is more convenient than an ordinary galvanometer with a magnetic system, because there is no suspension, no lamp and scale, and practically no leveling. An abstract of his paper is given in the Lond. *Elec.*, December 26th.

*Measuring Voltages with the Telephone.*—The telephone has been used for a long time in Kohlrausch's method of measuring the conductivity of electrolytes, but FISCHER has recently extended its application to measuring an e. m. f. or a potential difference, which then enables him to also measure a current by determining the potential difference at the ends of a known resistance. It is based upon Poggendorf's compensation method, as may be seen from the adjoining diagram, in which *a b* is a measuring wire and *c* is a sliding contact; *L* is a battery or other source of current. Between *a* and *c* there are, on the right, the switch S, then the telephone T, an electromagnetic interrupter, a resistance of two coils of 1,000 ohms and of 100,000 ohms, the latter of which can be short circuited, and a switch L, which enables one to put into circuit either a Weston standard cell or the e. m. f. which is to be measured. His electromagnetic interrupter, in which a vibrating spring is used, gives about 600 interruptions per second. The measurement is made after the circuit *a L b c a* has been closed for fifteen minutes. For instance, the problem may be to measure the e. m. f. of a Clark cell on the basis of the e. m. f. of the Weston cell of 1.0100 volts. By means of the switch L, the Weston cell is inserted into the circuit H, which is still open at S. The 100,000 + 1,000 ohms are inserted, and *c* is placed in the center of *a b*, say, on the division 500 if the whole scale is divided into 1,000 parts. The interrupter is then set into action, and the circuit H is closed at S. The telephone will then make a sound; the sliding contact *c* is then moved, say, to 502.0, where the telephone is silent. It starts again when *c* is on 518, hence the minimum is between 502.0 and 518.0;



MEASURING VOLTAGE WITH THE TELEPHONE.

*c* is then placed on 510, which is the middle point between 502.0 and 518.0, and the resistance of 100,000 ohms is short circuited. If, by chance, 510 is the correct point, the telephone remains silent, otherwise it will sound. By an actual test, it was found to be silent between 513.4 and 513.2. The e. m. f. of the Weston cell is therefore assumed to correspond to 513.3. Now circuit H is opened, the switch L is changed so that the Clark cell is inserted instead of the Weston cell and the whole operation is repeated. The e. m. f. of the Clark cell was thus formed to correspond to 719.3 lines of scale; hence it is $\frac{719.3}{513.3} \times 1.0100 = 1.4280$ volts, the temperature being 19.1° C. The value given by the Reichsanstalt is 1.4278. For another temperature it was found 1.4379, while the Reichsanstalt gave 1.4376. The method is therefore quite exact. The weak point in the method seems to be that it is assumed that the main current in the wire is absolutely constant. This could be avoided by the lower circuit duplicated, so that two observers could measure the two e. m. f.'s simultaneously on the same potentiometer wire. The present description is taken from an article in the *Zeit. f. Elektrochemie* January 1st.

*Measuring High Temperatures.*—FERY recently described a new method for measuring high temperatures, based upon the law of Stephan. According to this law, the heat transferred from a radiant body of the temperature T to another body of the temperature t is $A(T^4 - t^4)$ if both bodies have the emission capacity unity. If $t^4$ is small compared with $T^4$, the heat transferred is $AT^4$. According to Kerchhoff, the above condition of the emission capacity, being unity, if fulfilled for bodies inclosed on all sides. This is the case, for instance, in the electric furnace in which the opening through which the radiation passes is sufficiently small. In the author's apparatus the radiation is concentrated by means of a lense upon a thermo cell and its e. m. f. is measured. A comparison of his apparatus with the pyrometer of Le Chatelier gave differences of less than 1 per cent between 1,000° and 1,500° C., while below 600 degrees the differences were greater, on account of the smallness of the deflections of the instrument. The author determined by this method the temperature of the positive carbon of an electric arc lamp at 3,400 degrees. For very high temperatures, this method appears to be quite suit-

able. A fuller description can be found in the *Comptes Rendus*, v. 134, p. 977, and an abstract in the *Zeit. f. Elektrochemie*, November 20th.

## CURRENT NOTES.

American Electrochemical Society.—At the meeting of the Board of Directors, held at Philadelphia, Pa., on January 8th, the following new members were elected: Theron C. Stearns, Jersey City, N. J.; Abraham Van Winkle, Newark, N. J.; Prof. Chas. F. Chandler, New York; Dr. G. Drobegg, New York; Alfred Stansfield, Montreal, Canada; Dr. Victor Goldschmidt, Heidelberg, Germany; Dr. H. W. Wiley, Washington, D. C.; Samuel B. Devlin, New York; Joseph Wetzler, New York; Walter M. Stein, Prismos, Pa.; Dr. Charles Kellner, Vienna, Austria; Dr. Richard Hammerschmidt, Frankfurt a. M., Germany.

At the meeting of the Board of Directors on February 5th the following new members were elected: L. Seeger, New York; Dr. Rud. de Neufville, Frankfurt a. M., Germany; Dr. Hans Landolt, Turgi, Switzerland; J. M. Morehead, Chicago, Ill.; Wm. Smith Horry, Niagara Falls, N. Y.; C. I. Zimmerman, Madison, Wis.; John W. Schlegel, New York; Craig R. Arnold, Sharon Hill, Pa.; A. J. Rodgers, Milwaukee, Wis.; O. M. Thowless, Newark, N. J.; Godfrey L. Cabot, Boston, Mass.; Joseph B. Hall, Chicago, Ill.; Francis W. Higgins, Niagara Falls, N. Y.; Robert S. Allyn, New York; Ralph McNeill, New York; Takakichi Nakayama, Kochi, Japan.

The annual meeting of the American Institute of Electrical Engineers will be held in June, at Niagara Falls. It was found impracticable to arrange a joint meeting of the American Institute of Electrical Engineers and of the American Electrochemical Society in the autumn at Sault Ste. Marie.

Water-power in Norway.—According to a report from Christiana, the Rjukanfoss, in Telemar, known as the Norwegian Niagara, has been sold to a Swedish industrial trust, which will develop its power.

Stevens Institute of Technology.—Mr. Alexander C. Humphreys was formally inaugurated as president of this institute on February 5th.

St. Louis World's Fair.—It is announced that the grounds and buildings will be dedicated on April 30th by the President of the United States, and an address will be delivered by ex-President Grover Cleveland.

Wellesley College is to have, through the generosity of Mr. John D. Rockefeller, an entirely new and up-to-date power plant. Apparatus will be installed for heating all the buildings on the college grounds, which extend over several acres, and the grounds will be lighted by electricity throughout. Electric motors also will be used for operating elevators and blowers for ventilation purposes. Mr. Rockefeller has recently purchased from the Westinghouse Electric and Mfg. Co. for this plant two alternating-current, engine type, two-phase alternators, separately excited, one of 150 kilowatts and one of 75 kilowatts; also a five-panel switchboard.

## *Book Reviews.*

The Electro-Plating and Electro-Refining of Metals. By Arnold Philip. London: Crosby Lockwood & Son; New York: D. Van Nostrand Co. 680 pages. Price, $4.50.

This volume is a new edition of a well-known work, being in the main a reproduction of the last edition of Watt's "Electrodeposition." Chapters on electrometallurgical operations, including the electrorefining of copper, gold, silver, lead and nickel, treatment of tin, production of aluminium, and electrogalvanizing have been added with the view of bringing the work to date.

The book has its chief value in its historical treatment of questions relating to the deposition of metals, and covers quite extensively the field of electroplating in referring to the workshop details of various operations connected with the treatment of metal surfaces.

In the preface, the author expresses a hope that his guiding principle of neglecting theory, except in the most superficial and sketchy manner, will be apparent. This hope can undoubtedly be realized, as not only is theory neglected, but even such well-established laws as those of Faraday, the basis of electrochemical calculations, are not even stated or used as guiding principles in the discussing of various processes. The author excuses this neglect by stating that "a technical text-book cannot and should not deal with explanations of underlying theory, but should assume them." Even should those desiring a text-book on this subject agree with the author on this point, an examination of this book may cause some wonder as to what underlying principles warrant certain statements, such as that on page 498, where it is claimed that the construction of dynamo machines used for copper refining "should undoubtedly be based upon the quality of copper which it is intended to refine by their agency. A dynamo which would fulfill all the requirements of electrolysis of one variety of copper would be unsuited for refining metal of higher resistance."

While we cannot overlook the many good features of Watt's book on electroplating it is difficult, in this day of more advanced electrochemical practice, to find justification for perpetuating statements such as the following which appear in the pages of this new edition. On page 487 a statement, that doubt may be cast upon certain laboratory tests, inasmuch as the current for making them was furnished by voltaic batteries, whereas dynamo current is used in practice, and on pages 313 and 334, that a satisfactory plating can be obtained in about one-half the time with dynamo current than it can with battery current, might convey the impression that current derived from a battery differs very materially in its electrolytic effects from that delivered by a dynamo.

While this work gives a large number of recipes for solutions, describes processes and operations used in connection with the treatment of metal surfaces and contains a fund of information useful to the plater, the instruction as far as it relates to electroplating practice, is decidedly of the rule-of-thumb order. There are few progressive platers, in this country at least, who would find in this book a satisfactory guide in their work. The ampèremeter is mentioned and illustrated in the early part of the book, but its use is hardly referred to throughout the part on electroplating. The effect of current density on character of deposit is not treated, nor are data for proper current density for various metals and solutions given. Information relating to current strength is occasionally lightly touched upon by phraseology, such as "a battery power of three or four pairs is required."

The modern plater is rapidly leaving the rule-of-thumb methods which characterized earlier plating work; he is being guided by theory and classified knowledge, and employing instruments which enable him to calculate and regulate his work to a considerable degree of precision. In using this book, which neglects such guiding principles, he may naturally feel that it is out of date, or written for the amateur rather than the practical man, when, as on page 297, he is advised to carry on the "dipping" operation near a fire-place or in the outer yard. He may also recognize a touch of humor on page 295 where, in describing the operation of the hot lye vat used for cleaning, it reads: "It is easy to ascertain if the potash has lost its caustic property by dipping the tip of the finger in the solution and applying it to the tongue." The positiveness of this method of testing is not a sufficient reason for recommending the tongue as a testing agent, especially where potassium cyanide is made free use of, as it is in many plating establishments.

The first two chapters of the book are new, replacing chapters I, II, III and V of the old book. They deal with the various sources and generators of electrical energy. It may

strike the reader as peculiar that as much space is given to description of the thermo pile, an apparatus which has never become of much practical importance, as is given to the dynamo. The author says that "there is only one form of dynamo which is of any practical use for the electro-metallurgist, and that is the particular form of machine known as the shunt dynamo." This statement could hardly have been made with a full knowledge of the advantages of compounding and of the compound-wound machines which are being installed in many plating establishments in preference to shunt wound dynamos.

The last 200 pages constitutes new matter added to the former work on electroplating. An admirable feature introduced here and one which is not often found in electrochemical books is the extensive treatment of the problem of copper refining from the financial or commercial standpoint. The author calculates the most economical current density, which is shown to depend upon various factors, such as cost of power, labor and rate of interest. He states that a similar line of reasoning may apply in calculation of processes of refining metals other than copper. While this is perhaps the best treatment of the problem which has been published, it is not entirely satisfactory. The counter-electromotive force of polarization which enters as a component of the electromotive force necessary for each tank is not mentioned, though it may play an important part. An item which enters largely in the cost of electrolytic refining of copper, and to a much greater degree in the case of other metals, is the cost of maintaining the solution in constant working condition, either by purifying or regenerating, or by making up new solution from time to time. This has not been included in the estimate of the cost of copper refining.

The new material added by the author has not the same fault of omitting the important working details such as current density and pressure as has the material taken from Watt's book. In the discussion of various processes, references are made to the leading literature on the subject. The author has been handicapped by limit of space for description of various processes and operations and the descriptions are thus somewhat incomplete and superficial. The last chapter, entitled "Electrogalvanizing," describes at length the Cowper Coles process of electrolytically depositing zinc upon iron, where insoluble electrodes are used. He does not mention, however, the processes used most exclusively in this country, which employ soluble anodes.

MONOGRAPHIEN UEBER ANGEWANDTE ELEKTROCHEMIE. Vol V: Die Herstellung von Metallgegenständen auf elektrolytischem Wege und die Elektrogravüre. By Dr. W. Pfanhauser. Halle: W. Knapp. Illustrated. Price, Marks 7.

The author is a manufacturer of machinery, apparatus and chemicals for electroplaters' use, and has thus been kept in touch with the practical side of the subject. He is also a theoretical man, and has written numerous articles for the European technical press. It is therefore not surprising to find in this book a good welding of the theoretical and practical.

The author first gives a brief review of the history of the various attempts to make metal articles by electrochemical means, and then proceeds with a clear, logical exposition of the chemical and electrochemical characteristics of the copper-plating bath. Numerous experimental facts are given, and the explanation of the formation of poor and irregular deposits is strictly scientific. The same phenomenon which has thrown so much light on the working of the lead accumulator—concentration changes in the electrolyte—plays here an equally important *rôle*. For instance, on page 8 it is stated that after seven hours of electrolysis the copper sulphate at bottom of vat was twice as concentrated as at the top. This fact was recognized some years ago by American electrolytic copper refiners. Improvements in the circulation of the electrolyte of the refinery has allowed them to use an increased current density.

The next chapter, on the physical properties of electro deposited copper, is very good, but this is a matter which has not yet been brought to a satisfactory basis.

The latter part of the book is taken up with the various processes for making metallic powders, foil, wire, pipes, thick sheets, etc.

There has been a vast amount of money spent in attempts to electrodeposit copper wire, because cathode copper has a conductivity some 2 to 4 per cent. higher than the same copper when cast from the "refining furnace." These attempts have met as yet with only failure. The Elmore process, it is true, has been brought to a practical producing stage, but its success has been in making pipes and not in making wire.

Another successful application of the electrodeposition of metals has been the manufacture of parabolic reflectors by Cowper-Coles.

In this country seamless copper floats for water tanks are made and some types of switches are electroplated, of which we find no mention in this book. Electroplating might be properly included, but it may be supposed that this other similar process will be treated in another monograph of the series.

It is quite noticeable that the average inventor has an ingenious disregard for commercial conditions. For instance, on page 74 is noted an invention for the direct production of wire. The imaginary cost sheet of the imaginary plant shows a profit of 28,670 marks, corresponding to a profit of 28 per cent. on the capital. Of this, 28,000 marks is due to gold and silver recovered from the anode slimes. These metals are, of course, paid for by any purchaser of "converter bars," and could be of little source of profit except as competing with the electrolytic refiners. There are on our Atlantic Coast half a dozen electrolytic plants in which copper can be refined from "anode to cathode," at a cost of from $3 to $5 per ton.

The last two chapters of the book treat of electrolytic etching and Rieder's electro-engraving process.

PRACTICAL PLATING AND POLISHING. New York: Zucker, Levett & Loeb Co. 114 pages, illustrated. Price, $0.80.

This small book is intended for the use of the practical electroplater. No attempt is made to give theoretical discussions or explanations, but the book is practical in every detail.

After an explanation of the most fundamental terms of electricity, directions are given for setting up and arranging the various apparatus of a plating plant. Then follow special chapters on nickel plating, copper plating, bronze plating, brass plating, silver plating, gold plating, tin plating and galvanoplating. The rules given are worded in concise and simple language, and technical terms are avoided as much as possible, evidently under the supposition that the average electroplater is neither a chemist nor an electrician.

## ELECTRIC GENERATORS FOR CHEMICAL PLANTS.

The increasing use of the electric current in chemical plants involves the question of proper generation of power. There are many factors deciding the location of an industry of this character, and it is not to be expected that all of them can center themselves about a source of energy such as we have in Niagara Falls. It therefore devolves upon the majority to generate their own power with the best means at hand. The prominent method is the use of a steam engine driving a direct current generator.

The requirements of electrolytic work are a large current at a low voltage. It is possible, however, to so assemble the various tanks or process vats that by placing a number in series we can prevent the use of generators of such an extremely low voltage as is called for in the electrochemical process. There are certain elements in the operation of the tanks or vats, however, which render it inadvisable to place too

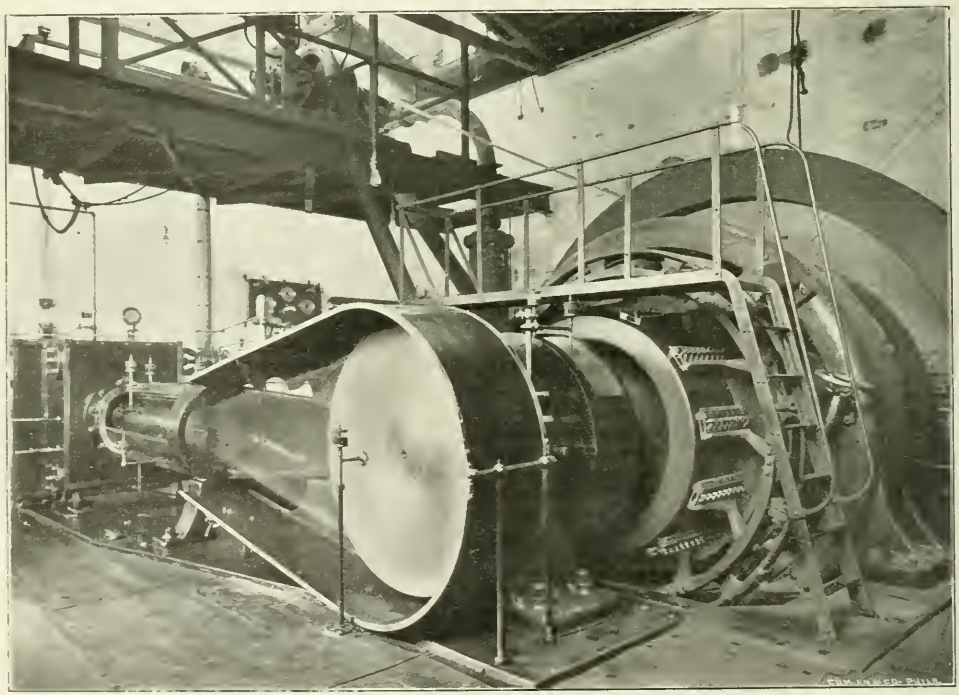
many units in series with the result is the use of generators ranging from about 70 to 125 volts.

It is the heavy current capacity, however, which specializes the generator used for electrochemical purposes, and the services of such a machine calls for the very best in electrical design and construction. The conductors must be amply large to carry the current imposed; the commutator must be of greater size than usual, and all ventilation possible given to the windings and commutator face. The brushes must be of sufficient size and a strong and satisfactory method supplied for transmitting the current from the brushes to the cables at the generator terminals.

The machine will be called upon for practically continuous operation, and abundant opportunity furnished for the observance of its durability and action under the constant full load. It is by the recognition of these facts that a manufacturing firm succeeds in the application of their generators to work of this character. The Crocker-Wheeler Co., Ampere, N. J., have frequently had occasion to apply their standard types of generator to the special work entailed in electrolytic service.

The photograph shown above is a portion of the plant of the Balbach Smelting and Refining Co., Newark, N. J. The cross compound Corliss condensing engines made by the Hewes & Phillips Co. are direct connected to a Crocker-Wheeler generator, furnishing 4,300 ampères at a pressure of 70 volts. The current is used principally in the electric refining of copper, for which this company have been prominently known for years. A smaller portion of the current is used in that part of the plant devoted to the refining of gold, silver and lead. Upon the gallery in the background of the cut is shown a dynamo, belt-driven from the large engine below, and furnishing current at 125 volts for the driving of the power motors and lights used about the works.

The main generating unit is interesting as being typical of this type of machine, with its large commutator face and high current output in proportion to the size of the generator. Other prominent electrolytic plants using Crocker-Wheeler generators are the Buffalo Smelting Works, Buffalo, N. Y.; the Perth Amboy plant of the American Smelting and Refining Co., and the De Lamar Copper Refining Works, Carteret, N. J., representing over 3,000 kilowatts of power.



PLANT OF THE BALBACH SMELTING AND REFINING CO.

## AN ELECTRIC PROCESS FOR PURIFYING WATER.

Electrochemical work, as applied to the purification of water, is the result of adapting well-known laboratory experiments to industrial practice on a large scale. We recently inspected a plant designed for this purpose and exhibited at the office of the American Electric Improvement Co., Philadelphia, Pa. While this is only an exhibit plant, the company state that the process, which is based upon patents of Mr. C. C. Clark, has passed the experimental stage, and that they are now filling orders for industrial plants.

The adjoining illustration, Fig. 1, shows diagrammatically the construction of the apparatus, the whole length of which is 10 feet. While at first sight the diagram may look somewhat complicated, the construction is really very simple, and may be easily understood; 26 is the water inlet and 52 the water outlet. The water, having entered the apparatus through 26, passes into the electric chamber, containing a series of electrodes 29 and 30. There is always a negative electrode following a positive electrode, and, *vice versa*, the positive electrodes being marked 29 and the negative ones 30 in the diagram. Connections of the electrodes with the positive and negative pole of the current supply are made by the wires 32 and 33, which pass through the cover of this box and are connected with the electrodes in the manner shown in the diagram.

The voltage used in the plant visited is 240 direct current. The electrodes are perforated, as shown in Figs. 3 and 4

While the water passes downward through holes 31 decomposition of the foreign substances takes place, and the mixture thus produced of purified water and of the products of the electrochemical decomposition leaves the electric chamber through the hole 42 in the bottom, and then enters the large and long cylinder 7.

While the water inlet 26 has a small diameter, this cylinder has a large diameter, the object being to produce a relatively low speed of flowing through the cylinder with the large diameter, in order to enable those products of decomposition which have a higher density than water to settle down, and those which are lighter, such as the gases developed, to raise upwards to the top of the cylinder.

The principle of the apparatus is therefore to first decompose the impurities in the water in the electric chamber, and, second, to remove afterwards these impurities by purely mechanical means in the large cylinder; 44 are the blow-off pipes for discharging the heavier impurities. In the plant visited a dark brown muddy liquid, nearly solid, was discharged through them. The gases which are developed are left off through 48. The water thus freed from its impurities is led off through the outlet 52.

The inventor states that various materials have been found to be suitable for the electrodes, but that he has obtained his best results with copper and Acheson graphite electrodes. It is claimed that the wear and tear of the electrodes is small.

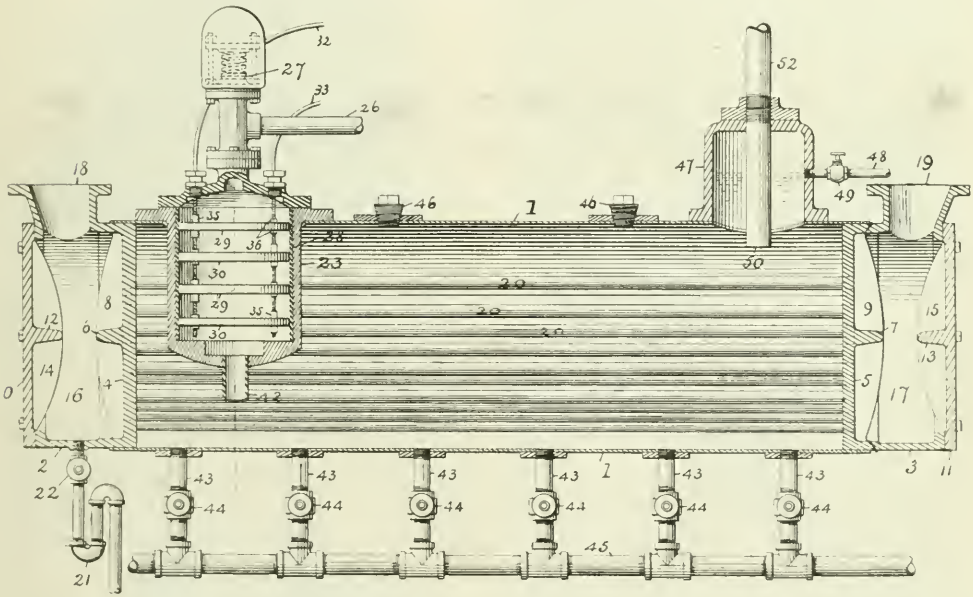
We may now describe the details of the apparatus. Referring to Fig. 1, the cylinder 1 is a close and tight receptacle, into the ends of which are secured circular heads having outer cylindrical rings 2, 3; inner plates 4, 5, which form tube sheets, with stiffening ribs 6, 7, 8, 9, removable covers 10, 11, with ribs 12, 13, 14, 15, so that circulating chambers 16, 17 are formed, having openings 18, 19, to which may be attached the necessary pipes to convey cooling water or steam into or out of chambers 16 and 17.

The tubes 20 extend from tube sheet 4 to tube sheet 5, their ends being secured in expansion stuffing boxes. Cold water is passed through these tubes for artificial cooling when salt water or other liquids of a high conductivity are electrolyzed. When used as a feed-water heater and purifier, steam is passed through the tubes 20, generally exhaust steam. A drain pipe 21 connects to the bottom of chamber 16, and valve 22 opens and closes the pipe, and is only used to take away the water of condensation when the apparatus is using steam.

26 is the inlet pipe for the inflowing liquid to be treated, and above it is located a suitable relief valve 27, having means to relieve any excess of pressure above a fixed limit.

The electric chamber 23 has an insulated lining 28. The method of suspension of the positive and negative electrodes 29 and 30 is best seen in Fig. 3. The current conductors 32 and 33 are are provided with insulation 35 and with conducting nuts 36. At the sides of the cover 24 are insulated stuffing boxes 37, the patented construction of which is best seen in Fig. 5.

The heavy impurities which settle down at the bottom of the cylinder can at any time be drawn off through the pipes 43, controlled by the valves 44 and connected to the discharge pipe 45. When a thorough cleaning is necessary, the wash-



APPARATUS FOR PURIFYING WATER.

out plugs 40, at the top of the cylinder, may be removed, giving access for the introduction of a hose.

In the dome 47 the light, floating impurities are gathered, which may be drawn off by the pipe 48, controlled by valve 49, while the outflow pipe 50, for the purified water, descends below the dome and into the cylinder to the body of pure water.

The action of the apparatus is continuous during the supply of liquid and electric current, and when once set in operation it is automatic, in so far as the electric current (furnished from ordinary constant potential mains, as for lighting, etc.) will vary according to the conductivity of the liquid to be treated, *i. e.*, the less impurities are in the water the greater its resistance and the smaller the current.

Fig. 2 is a cross section of the inlet chamber. Fig. 3 shows plainly the construction of the inlet chamber, and Fig. 4 is a plain view of the electrodes.

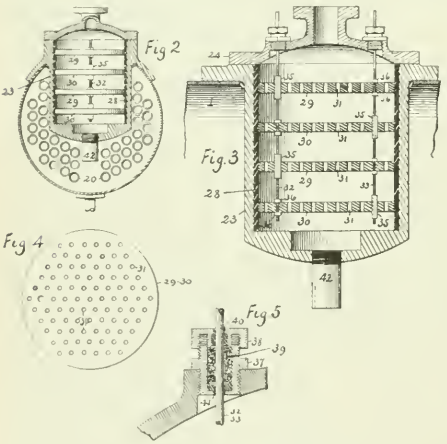
The apparatus is claimed to be suitable for a great many industrial purposes, the most important one being probably for the supply of pure water for boilers. Other applications are said to be the purifying of the water pumped from mines so that it may be used for commercial purposes; the changing of

sea water to fresh water for use on steamers; the purifying of water for manufacturing purposes, ice plants, hotels, office buildings, the purifying of sewage, etc.

The main point is, of course, the question of cost, and the inventor claims that in this respect his process is far superior to all other methods of purifying or distilling water. For an average price of electric energy (based upon the cost of generating electric energy by means of Corliss high-pressure engines, with a price of $2.50 for coal) he states that, according to a calculation made by an electrical expert, 360 gallons of fresh water can be purified at a cost of one cent by his process. This cost can still be considerably diminished if the most improved and most economical methods of power generation are applied, as found in modern power plants.

The cost for attendance is, of course, very small, as all the attendant has to do is to discharge the pipes 44 and 49 at intervals. There is no complicated device on the apparatus which might be liable to be destroyed by the carelessness of the attendant.

Another interesting application to which the apparatus is said to be well adapted is the purification and aging of alcoholic liquids. The liquor, after the treatment, is found to be pure. It is said that by this system whiskey direct from



DETAILS OF APPARATUS FOR PURIFYING WATER.

the distillery can be aged at a cost of 1½ cents per gallon, and that, after having been treated in the apparatus and stored in a charred barrel for thirty days, it is found to be equal to the best whiskey in the market. This method should therefore represent a great saving over present methods in the expenses for storing, interest and insurance. The apparatus used for this purpose contains a filter near the outlet, in order to remove impurities which have the same specific gravity as the liquor, and which therefore do not settle down or raise up in the large cylinder. Otherwise the apparatus is the same as that for purifying water.

## ELECTROPLATING DYNAMOS.

The building of a dynamo for electroplating or any low voltage work involves difficulties not encountered in ordinary machine design. Of course, the two great problems to be met lie in taking care of the heavy current without undue heating, both in the windings and at the commutator, and in the prevention of destructive sparking at the brushes. In other words, commutating the relatively large amount of current. Scientific design will avail nothing in this branch of the work without a generous allowance of iron and copper.

The Holtzer-Cabot Electric Co., Boston, Mass., are manufacturing a line of machines designed especially for work of electrochemical nature. A cut of one of the machines is shown herewith, the machine in question being capable of delivering 700 ampères at 6 volts. It will be noted that the machine is quite compact, this being necessary to ensure short, massive magnetic circuits, giving economy of exciting energy. These machines are made in two, four, six or eight-pole designs, according to the size. The armature is shown in Fig. 2. The coils are arranged cylindrically around the armature, and are made of heavy copper bars, the length being just great enough to enable a loop of the proper span to be formed. An exceedingly important feature in machines of this kind is the armature resistance, which is quite low in these machines, owing to shortness of the circuits. The windings are so

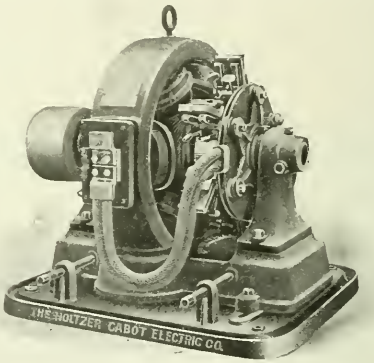


FIG. 1.—ELECTROPLATING DYNAMO.

arranged that the air may circulate freely through the conductors for ventilating purposes, which is also important. The arrangement of the armature conductors is such that, in case of injury, a coil may be replaced by simply lifting a few of the adjacent coils, it being unnecessary to strip the armature, as would be the case in many forms of windings.

The commutator is necessarily of heavy construction, with sufficient copper to make the current density very low, leaving a wide allowance for frictional heat due to the unusual area of brush surface. These segments are of pure copper, rolled to increase their density, thereby giving greater conductivity and lengthening the life of the commutator. The brush holders

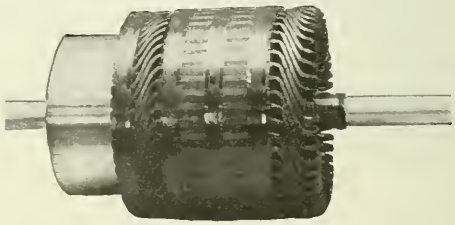

FIG. 2.—ARMATURE.

are of the tangent type, and are made especially for the carrying of heavy current. The spring is flat and loop-shaped, and is long and heavy, allowing extremely delicate adjustment, so that the brushes are held upon the commutator with a firm pressure, but without causing undue frictional heat. Provision is made for carrying the current from the brush itself to the portion of the holder which clamps the stud, so that the spring or sliding contacts are not depended on to carry current. The pedestals are so arranged that upon occasion the armature may be removed without disturbing the connections, it being simply necessary to raise the brushes and slide off the front or rear pedestal, carrying it out of the way in order that the armature may be removed. Compound winding is usually employed.

On larger machines it is often necessary to employ a double

commutator. Fig. 3 shows a machine of this kind, built by the Holtzer Cabot Electric Co., for delivering 4,000 amperes at 6 volts. This machine is intended primarily for the electrolytic reduction of copper ore, but is, of course, suitable for any work requiring a large quantity of current at a low voltage. In this machine the poles are eight in number, and are of wrought iron, cast welded into the ring. The poles are fitted with a special form of shoe, which is of such a shape as to pre-

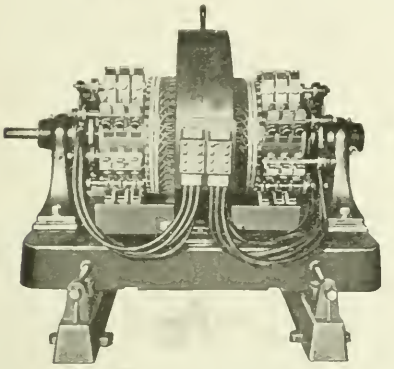

FIG. 3.—4,000-AMPERE DYNAMO.

vent the field flux from being distorted by the back magnetization of the armature. Thus the diameter of commutation remains constant, and it is not necessary to shift the brushes with changes of the load. The armature for this machine is assembled on a spider, provision being made for circulation of the air through the inner parts of the machine and out through the winding. On all these low-voltage dynamos the speed is made purposely quite low to reduce friction as much as possible and secure cool and efficient operation.

## *Personal.*

DR. J. J. THOMSON, of Cambridge University, England, has been appointed head of the department of physics of Columbia University, New York City, to succeed the late Ogden Nicholas Rood. Prof. Thomson was born in 1856, and is best known by his famous researches made in recent years on corpuscles or "masses smaller than atoms."

MR. CRAIG R. ARNOLD, of Philadelphia, is going to the South, and to Mexico, to report on the application of electrolytic gold processes to certain mines.

MR. J. WALTER WELL has resigned the position of Provincial Assayer for Ontario, in order to specialize along certain lines affecting the mining industry in Ontario. Mr. A. G. Burrows has been appointed to succeed him.

MR. ANDREW CARNEGIE has notified the Provost of Greenock, Scotland, that he is prepared to give $50,000 to erect a memorial to James Watt, the inventor, who was born in that city on January 19, 1736, in recognition of his engineering achievements; or he will head a movement in America to raise a large fund which, in conjunction with sums raised in Great Britain, will provide for a more extensive scheme of commemoration.

COUNT CORRADO EMO-CAPODILISTA, of Milan, Italy, was recently in the United States for the purpose of making a study of the electrical and electrochemical industries as developed here.

MR. GEORGE H. GIBSON has resigned his position with the Westinghouse Co's publishing department, Pittsburg, Pa., to accept a position with the B. F. Sturtevant Co., Jamaica Plain Station, Boston, Mass., the well-known manufacturers of blowers, heating, ventilating and forced draft apparatus, electrical machinery and steam engines. Mr. Gibson was formerly a member of the editorial staff of the *Engineering News*, of New York City, and is a graduate of the Engineering School of the University of Michigan.

## OBITUARY.

We regret to report the death of MR. A. T. WEIGHTMAN, who was well known among the electrochemical fraternity of this country as the electrochemist to the Electrical Lead Reduction Co., Niagara Falls, N. Y. Owing to failing health, he recently resigned this position and went to England to recuperate. He died in London, on February 3d. He was a member of the American Electrochemical Society, and at the Niagara Falls meeting he read a paper on the scientific principles of the Salom lead-reduction process.

## INDUSTRIAL NOTES.

THE OHIO BRASS CO. have decided to substitute alternating-current power distribution for the direct-current system at present in use in their shops at Mansfield, Ohio. A recent purchase from the Westinghouse Electric and Mfg. Co. comprises a 180-kilowatt, 7,200 alternation, two phase alternator, a direct-current exciter, switchboard equipment and the following induction motors: two of 40 horse-power, four of 30 horse-power, one of 20 horse-power, one of 15 horse-power and one of 2 horse-power. The alternating-current motors have been chosen on account of their low cost of maintenance and freedom from break-down.

THE SUSQUEHANNA IRON AND STEEL CO., Columbia, Pa., are about to install an electric-power distribution plant in their mills. A recent purchase from the Westinghouse Electric and Mfg. Co. comprises a 400-kilowatt alternating-current generator, one 200 horse-power induction motor and 300 to 400 horse-power in motors, ranging in size from 50 to 20 horse-power.

THE AMERICAN ELECTRIC IMPROVEMENT CO., Philadelphia, Pa., are installing a water-purifying plant for the T. A. Harris Co., Continental Dye Works, Philadelphia, Pa.

THE ANACONDA COPPER MINING CO. are about to put in operation a new 5,000-ton-per-day reduction plant, which will be equipped with electrical apparatus for power distribution. A recent contract with the Westinghouse Electric and Mfg. Co. embraces seven motors, of an aggregate of 185 horse-power, to be added to the present installation of about 30 Westinghouse motors, of an aggregate of over 1,000 horse-power.

THE ST. JOSEPH AND ELKHART POWER CO., Mishawaka, Ind., are installing a large hydraulic plant on the St. Joseph River, near Mishawaka, including power house, dam and hydraulic and electric equipment, for the generation and transmission of electric power to the cities of South Bend, Mishawaka and Elkhart, Ind., and adjacent territory. The energy will be used for general lighting and power purposes. The consulting engineers and general contractors for the complete development are Sanderson & Porter, 31 Nassau street, New York City, who have recently purchased from the Westinghouse Electric and Mfg. Co. four 1,000-kilowatt, 13,200 volt, revolving field alternators and two 125-kilowatt, direct current exciters. The machines are all to be direct coupled to horizontal-shaft water wheels.

TRADE CATALOGUES.—We have received trade catalogues from the following companies: Fort Wayne Electric Works, Bulletins 1,037 and 1,038 (Mast arms). The B. & B. commutator towing device) and flyers 4,040 and 4,041 (Primary fuse boxes. Type a transformer "strikes"). Fred. M. Locke, Victor, N. Y. (Victor insulators). Alphaduct Mfg. Co., New York (Alphaduct flexible conduit). Alberene Stone Co., New York (Alberine stone for use in high potential work). Crouse-Hinds Electric Co., Syracuse, N. Y. (Norbitt porcelain electrical appliances).

THE MATLACK PLATINUM WORKS, Sugartown, Pa., owned by J. Bishop & Co., were recently destroyed by fire, which was started by burglars.

THE MEXICO MINE AND SMELTER SUPPLY CO., Mexico City, Mexico, have recently ordered several centrifugal pumps from the Morris Machine Works, New York, N. Y.

## DIGEST OF U. S. PATENTS PRIOR TO JULY, 1902.

*Compiled by Barnes & Townsend, Patent Lawyers, National Union Building, Washington, D. C.*

*This digest of electrochemical United States patents prior to July, 1902, will be one by classes, setting out for comparison in each class those devices which have the same object, or those methods which seek the same results. In each class the patents will be arranged chronologically. The digest will be complete in the sense of covering every point which is touched upon in the original specification.*

(Continued from page 196.)

518,710. Henry Carmichael, Malden, Mass., April 24, 1894.

Rectangular vessel has sides of glass or slate and trough-shaped bottom of iron, with vertical parallel ribs, serving as cathode. Anode compartment, a rectangular box having a trough-shaped bottom of asbestos, stiffened with hydraulic cement, resting on cathode ribs. Sides of vessel extend up around sides of anode compartment, and serve to collect hydrogen. Some of the cathode ribs extend up into the hydrogen-collecting chambers. Anode, lumps of gas carbon or magnetite, supported on a net of platinum wires carried by platinum pegs, which pass into an insulated frame and conductor of heavy copper wire. Gradually feeds brine into cell through perforated pipes opening upwardly against anode, thus washing it and maintaining a zone of brine between anode and cathode. May suspend basket of salt in anode compartment. Cathode ribs direct caustic to middle of bottom, along which it flows, increasing in concentration, to an outlet at one end. A siphon delivers caustic in drops through a layer of petroleum, preventing short circuit and excluding air. Caustic diffusing through diaphragm conducted back by a horizontal pipe lying on diaphragm, and opening through it into cathode compartment at end remote from outlet. Inflow of brine proportioned to outflow of caustic, and causes downward movement in anode compartment, hindering upward diffusion of caustic. Increases difference of specific gravity of anode and cathode solutions by surrounding anode compartment with lagging to retain heat, while iron base and ribs conduct away heat. Base may also have external corrugations. Delivers a broken stream of brine to the feed pipe by a rotating scoop. Shows a plurality of cells electrically connected in series, with common supply and discharge pipes.

A second form of apparatus employs a circular glass bell and iron base, between which is clamped a conical diaphragm, delivering the hydrogen to a central collecting chamber. Radial cathode ribs on the base form a tortuous passage, delivering caustic to a central outlet. Pipes for supplying brine and delivering chlorine and hydrogen pass through base. Cathode ribs may extend upwardly into hydrogen chamber.

A third form of apparatus for electrolyzing sodium sulphate, similar to second form, but has side outlet for sulphuric acid.

522,615. Isaiah L. Roberts, Brooklyn, N. Y., July 10, 1894.

Vessel, a U-shaped glass tube, with central supply pipe. Salt fills pipe and bend of tube, serving as diaphragm. Anode, limb of U tube filled with broken coke or charcoal, receiving a carbon rod conductor; iron cathode in other limb. Caustic outlet in bend. Modification, using rectangular vessel, divided transversely by a narrow, perforated box of glass or stone ware, filled with salt. Anode compartment filled with broken carbon.

522,616. Isaiah L. Roberts, Brooklyn, N. Y., July 10, 1894.

Iron vessel, serving as cathode. Diaphragm, a bag of wire netting and cloth or asbestos, within which is a perforated or porous jar of unglazed porcelain, the space between being filled with sand or powdered anthracite. Porous jar filled with salt, into which depends the charcoal anode. Cell closed at top by wood or tile, soaked in paraffine and wax. Glass ring insulates diaphragm from iron vessel. May use tubular charcoal anode, receiving a perforated salt-supply pipe.

522,617. Isaiah L. Roberts, Brooklyn, N. Y., July 10, 1894.

Similar to preceding, but has drain pipe from anode compartment to remove such impurities as sulphuric acid and chlorides or sulphate of aluminium, iron and calcium.

522,618. Isaiah L. Roberts, Brooklyn, N. Y., July 10, 1894.

Same as 522,616.

525,732. September 11, 1894; Emile Andreoli, London, England.

A series of narrow anode and cathode compartments are separated by diaphragms of porcelain, made of powdered pumice and asbestos or infusorial earth. The anodes may be of metal, e. g., iron, peroxidized lead or platinum, or of retort carbon, ground flat on side facing cathode. Anodes have necks passing through holes in a slate cover, a tight joint being made by a cement of ground asbestos, porcelain and litharge, and by a winding of paraffined string. A system of pipes gives a forced circulation through all the compartments of each cell and through several cells in succession.

534,033. February 12, 1895; Thomas Craney, Detroit, Mich.

Evaporates caustic soda solution in cast-iron kettles, and passes an electric current from a carbon anode to each kettle to purify solution. Current converts metallic oxides dissolved from metal of kettles into insoluble higher oxides, which settle out.

541,146. June 18, 1895; Henry Blackman, New York, N. Y.

Returns brine to cell, after saturating and cooling it. Cooling pipes pass through cell. Shows various cells, one containing a series of alternating plate electrodes of platinum and zinc.

549,189. November 5, 1895; Thomas Craney, Bay City, Mich.

Anode compartment, a vessel of perforated metal or wire cloth, serving as cathode, lined with asbestos. Sides have an insulating lining. A body of broken carbon rests on the asbestos and serves as anode, contact being made by protected carbon pencils depending into it. Outer vessel of iron, which may also act as cathode. Pipes lead to and from anode and cathode compartments.

552,895. January 14, 1896; Thomas Craney, Bay City, Mich.

System employing a tandem series of the cells shown in patent 520,257. Pipes connect anode and cathode compartments respectively. Anode solution from last cell freed from chlorine and returned. Caustic solution from last cell falls through a carbonating tower, and may be converted into either normal or acid carbonate. If normal carbonate, it dissolves, heat being used if necessary, but is partially precipitated in a cooling tower, the residual solution returning to cathode compartment of first cell. Bicarbonate precipitates partly in carbonating tower and partly in cooling tower. Conveyer removes carbonate to a draining bin.

552,955. January 14, 1896; Thomas Craney, Bay City, Mich.

Solution from last cell descends through a high stand pipe against a rising stream of carbon dioxide. Bicarbonate removed from bottom, partially dried in a centrifugal, fully dried by a mixture of hot air and carbon dioxide, and ground. May wash out any traces of salt by a bicarbonate solution thrown into centrifugal. Residual monocarbonate solution from a stand pipe returned to cathode compartment of first cell.

559,038. March 10, 1896; Michael H. Wilson, Brooklyn, N. Y.

Electric current carried to and from electrolyte by two falling streams of water flowing through or around metallic terminals above cell. Water streams may fall free or descend through vertical, perforated glass tubes, opening through top and bottom of cell. Partition depends from cover of cell, partially dividing salt solution.

560,518. May 19, 1896; Jules Meyrueis, Paris, France.

Diaphragm cells arranged in cascade. Pipes carry electrolyte through successive cathode compartments. Acidifies concentrated brine in anode compartments with hydrochloric acid. Delivers caustic solution to a boiler containing litharge, which dissolves and is re-precipitated as white lead by a stream of carbon dioxide. Residual liquor further carbonated and sodium bicarbonate crystallized out. Solution then returned to cells.

## THE BRUSH STORAGE BATTERY PATENT.

Secondary or storage batteries, consisting of lead and lead peroxide electrodes in sulphuric acid, were the first electric accumulators of any practical value. In 1856 Gaston Planté began his investigations, which extended over a period of several years, on the formation of accumulators of this type. His method of formation was purely electrochemical, starting with metallic lead, in the form of sheets, which he submitted to the action of an electric current in dilute sulphuric acid. His process was tedious and expensive, requiring a great number of reversals with intermissions of repose on short circuit. On account of the enormous expense of converting metallic lead into active material by this original Planté process, the *original* Planté battery cannot be said to have ever had a commercial existence.

On October 20, 1880, Camille A. Faure, a Frenchman, patented in France an improvement on the Planté battery, which consisted in mechanically applying active material to a conducting support, thus producing instantly a plate, the manufacture of which by the original Planté process required months. A corresponding patent was issued to Faure in the United States on January 3, 1882, No. 252,002. On March 2, 1886, United States patent No. 337,209 was issued to Charles F. Brush, Cleveland, Ohio, covering this same invention. After years of litigation and the expenditure of large sums of money, the United States Circuit Court of Appeals handed down a decision on October 4, 1892, in a suit of the Electrical Accumulator Co., owning the Faure patent, against the Brush Electric Co., owning the Brush patents. The court upheld the Brush patent, No. 337,209.

Some portions of this famous decision are of lasting interest, and are worth recording even at this late date:

> (3) The invention described in letters patent No. 257,005, issued January 3, 1882, to C. A. Faure, a citizen of France, for an improvement in secondary batteries, having been conceived by the patentee in France, and being covered by a French patent issued October 20, 1880, he cannot claim the invention in this country prior to the latter date, as against a citizen of the United States who, being an original inventor, subsequently received an American patent.
>
> (5) Brush's patent, No. 337,209, was not anticipated by the patent of April 3, 1866, to George G. Percival, for secondary battery electrodes, consisting of cells filled with coarse conducting powder and divided by a porous partition, or by the patent of April 23, 1867, to George L. Leclanche, for a "polarization apparatus or electric accumulator," consisting of two plates of graphite or unoxidizable metal buried in two flasks of powdered graphite moistened with a liquid which is a good conductor, such as potash water.
>
> (9) The Brush patent, No. 337,209, was not invalidated by patents Nos. 260,653 and 276,155, issued to him prior to 1886 for improvements subsidiary to the main invention, for their subsidiary character appears on the face of such patents, although, owing to delays in the Patent Office, they were issued before the patent for the main invention.
>
> (10) The Brush patents, Nos. 337,209 and 260,099, did not expire with the Italian patent issued to him August 8, 1882, for division D of the Italian patent was designed to cover, not the

[illegible] mechanical operation made in 1882, of plates specially prepared for the purpose of more rapidly forming active material thereon by the Planté method of electrical disintegration.

(III) The Brush patent, No 260,090, must be limited to electrodes on which the active material is made by applying the Plante method of electrical disintegration or other "forming" process to plates which are ribbed, honey-combed, studded or equivalently prepared.

(IV) When an inventor makes a generic invention, and also subordinate specific inventions, and presents the whole series in a set of contemporaneous applications, he cannot be allowed, by subsequent amendments, couched in general terms, to enlarge the boundaries of each invention so as to extend each into the borders of another, and thus obtain a series of overlapping patents.

Patents Nos. 260,653, 260,090 and 276,155, referred to above, were patents issued to Brush for subsidiary improvements prior to the issue of his broad patent, No. 337,299, in 1886. It was held by the defendants that division D of an Italian patent, issued to Brush on August 8, 1882, disclosed the invention claimed in Brush's broad patent of 1886. This claim was overruled, as shown above. Had this defense been successfully maintained, the Brush patents would all have expired in this country August 8, 1887, or about a year after the issue of the principal patent.

Immediately after the issue of the Faure patents, and as a consequence of the notoriety given to the invention by Lord Kelvin's sensational announcement that he could hold in his hand in a small box 1,000,000 foot pounds of stored energy, the field of storage-battery research became the most extensively worked of any subject of electrochemistry. Hundreds of inventors began to work all the probable changes of form in the "grid" or conducting support. An idea of the activity in this field may be obtained by considering that prior to the Faure patent, No. 252,002, there had been issued in the United States in the whole only nine patents on storage batteries. In the first year following the issue of the Faure patent 27 United States patents were granted on this subject; in the second year 43, and in the following years 37, 25, 23, 18, 50, 93, 92, 36, 43, 35, 32, 28, 30, 42, 27, 45, 53, 52, 94. The last figure refers to a little more than a year, as it comprises all patents issued since January, 1902, up to date. It will be seen that there was an immense activity immediately following the Faure patent, and that, while this activity was greatly abated during the period of litigation, there has not been a year in which the number of patents issued was less than twice the total number issued prior to the Faure patent.

The commencement of litigation, involving the mechanical application of active material to a conducting support, caused attention to revert again to the Planté method of formation, it being desired to find some method of avoiding the Faure and Brush claims without the expense and waste of time necessitated by the original Planté method. It was soon found that the corrosion of metallic lead with the formation of active material not mechanically applied could be accomplished in a comparatively short time, and even in a few minutes, by using oxidizing electrolytes instead of sulphuric acid, or in addition to sulphuric acid. It was found also to be practicable to convert the metallic lead by purely chemical means, without an electric current, into active material, which was equally adherent and efficient with the mechanically applied.

These discoveries, it will be seen, practically disarmed the owners of the Brush and Faure patents, hence it does not seem probable that the recent expiration of the Brush patent, No. 337,299, will have any very marked effect upon the commercial aspect of the storage battery. This is particularly shown in the fact that the leading storage-battery company of this country, and the one which has controlled the Brush patent, have for a number of years, to a large extent, abandoned the mechanical application of active material.

It has been found by the company referred to that for most purposes positive plates made by a modified Planté or electrochemical process, and negative plates made by casting a grid around a compound of lead, and subsequently reducing the same, have been more satisfactory than the mechanically applied or "pasted" type. It is worthy of note in this connection, however, that one of the most recent and apparently successful types for the specific purpose of operating automobiles is of the pasted type which has now become public property. There is no telling what effect the expiration of the Brush patent may have on the commercial development of this particular type of batteries for automobile purposes.

## PROGRESS IN ELECTRIC-FURNACE WORK.

It is a curiously persistent and recurrent feature in the development of almost all new arts that after the disclosure of the new field paths are found leading into it from every direction, and the feeling is rather one of wonder that it remained so long undiscovered than of surprise at its discovery. Thus, after the development of the first reproducer of speech, it became apparent that a wide range of devices, from the arc to the electroplating vat, could be so manipulated as to produce the effects. Again, the discovery of new sources of the Becquerel rays and allied emanations have proceeded apace, until it would almost seem that in the end their presence will be detected wherever energy is undergoing transformation.

The history of the rise of the carbide art is an instance in point. The carbides of iron had long been known, and that of aluminium was discovered in the early days of electrometallurgy. Later the investigations of Moissan discovered a series so complete, so varied and yet so interrelated as to rival in theoretical interest any of the organic series. And now a very practical question with metallurgists is how *not* to get a carbide.

Among the abstract of current electrochemical patents in this issue is a description of a patent to Edward G. Acheson, which marks the solution of this problem for the case of aluminium, and perhaps of silicon. Of these, the former is readily obtained in a high state of purity by an electrolytic method, and the latter by any one of several special metallurgical processes. But the simple and brilliant conception that the carbon core of an ordinary electric resistance furnace may be eliminated from the equation, representing the reduction by means of a refractory heat-conducting sheath, and that for this sheath the most refractory carbides possess every essential qualification, seems destined to play an important part in electrometallurgy.

## ELECTROCHEMICAL METHODS IN THE IRON AND STEEL INDUSTRY.

The greater the practical importance of a special field becomes in the development of an industry, and the larger the capital invested in enterprises of such a special field, the greater will be the tendency to differentiation and specialization on the part of the engineers and scientists interested in this special field. This is as it should be. It is a historical fact that the immense industrial developments of recent years were due to differentiation and specialization.

On the other hand, no special industry should lose sight of the development of its sister industries. The development of the whole is always bound to benefit the parts. Therefore, while specialization is the keyword of progress, every progressive engineer and scientist must keep himself informed of the progress in other fields in order to take advantage of it in his own special field.

We are glad to note that Electrochemical Industry, while primarily devoted to the interests of electrochemical engineers and scientists, is also read with steadily-increasing interest by the engineering world in general. In fact, it becomes more and more evident that there is really no branch of engineering which cannot in some way benefit from the recent developments of the art of electrochemistry.

The iron and steel industry has long become of such immense practical importance that it is now considered as a separate industry. There are many books and university courses on general metallurgy in which iron is not dealt with, because, on account of its practical importance, the iron industry is considered as a special metallurgical industry. Nevertheless most of the progress of this industry in recent years has been due to the fact that the most progressive managers and engineers in this field availed themselves of the possibilities offered by the development of other industries.

It is superfluous to speak at length of the wonderful progress which has been made in the iron and steel industry by the introduction of the use of electric power. We may simply refer to some remarks made by Mr. George Westinghouse in a recent speech in London, which was printed in our February issue. As an example, he stated that as a consequence of the progressiveness of the general manager of the Homestead Works of the Carnegie Co. in introducing electric power for any possible purpose, this company produce, with about 4,000 men, three times as much steel as the famous Krupp Works produce with 15,000 men.

The introduction of electric power in iron and steel works may become of immense importance for the introduction of electrochemical methods in such works. When electric current is available, the trial of electrochemical methods becomes an easy matter. The problem of melting iron and making steel in the electric furnace appears to be one of the most fascinating problems of modern metallurgy. Especially abroad, in France and Italy, a number of well-known metallurgists are endeavoring to find an economical solution of the problem. On the other hand, there are many who claim that, in view of the very high economy of the modern blast furnace, there is no danger, in the near future, of the electric furnace superseding the blast furnace. The principal question is, of course, that of cost, and it can readily be seen that the answer to the question whether it would pay to use an electric steel process will greatly depend upon local conditions, upon the cost of power and the cost of fuel. For the present we purposely refrain from discussing the general problem.

What we believe to be most needed at present for an understanding of the problem are facts on electric steel processes actually in operation. Such facts we intend to present to our readers in a series of articles, based directly upon authoritative information given by the engineers in charge of such work. In our January issue we dealt with a French plant using the Keller process; in our February issue we printed an article by Mr. Marcus Ruthenburg on his process, now worked at Lockport, N. Y., and in our present issue we publish an article on the Stassano process, in operation in Italy. We intend to continue this serial in future issues. Of the three processes so far described by us, the Keller process and the Stassano process apply the ordinary electric-furnace methods to the manufacture of steel, while the Ruthenburg process is interesting, as in it magnetic and electric means are combined in a decidedly novel manner to produce the desired results.

While we wish to refrain at present from discussing the principle of the use of electric-furnace methods in the iron and steel industry in general, we may emphasize the great advantages of such methods for the manufacture of special steels, such as tool steels. The present methods of manufacturing such special steels are expensive, and the advantages of electric-furnace methods for this special purpose are evident. It does not appear to be risky to prophesy that it is in this special field that the commercial invasion of electric-furnace methods in the iron and steel industries will be made.

Electric furnace methods are, however, not the only electrochemical methods which will prove of importance in the iron and steel industries. An entirely different example of what electrochemistry can do for these industries is the Goldschmidt "thermite" process of producing high temperatures. The latest developments of this process, with applications to iron and steel, were dealt with in an article by Mr. G. P. Scholl in our January issue. True, the Goldschmidt process is a purely thermochemical process, but it must not be forgotten that it could become of practical importance only after the price of aluminum had been reduced by electrochemical methods. In fact, we have here a special case of the general rule that electrochemical methods enable us to store energy in chemical products, and that the energy thus stored may afterwards be used for other purposes. The calcium carbide and acetylene industry is another example of the same general rule. We may mention in this connection that in recent years calcium carbide has been tried in a similar way as a reducing agent in metallurgical processes. We mention these facts as a proof that the electrochemical methods in the iron and steel industries are not restricted to electric-furnace methods.

## NEW YORK MEETING OF THE AMERICAN ELECTROCHEMICAL SOCIETY.

The third general meeting of the American Electrochemical Society will be held in New York City, April 16th, 17th and 18th.

Members and guests will please register at the Chemists' Club, 108 West Fifty-fifth street, and receive their badges as soon after their arrival as possible. Badges will be given to all members in good standing and to applicants who have deposited their initiation fee. Special badges will be provided for guests, who must be introduced by a member.

All meetings will be held in the large assembly hall of the Chemists' Club, where members in attendance may have their mail addressed, and where all announcements will be made.

By the courtesy of the Chemists' Club, its club house, including the library of the American Chemical Society, will be open for the use of members and visitors.

By the courtesy of the German Liederkranz, its club house, 111 to 119 East Fifty-eighth street, will also be open to members and guests during the convention. Membership buttons will secure admittance.

On Thursday morning, April 16th, at 9 A. M., a meeting of the Board of Directors will be held, which will be followed, at 10 A. M., by the business meeting of the Society, at which reports of directors and officers will be presented.

Reading and discussion of the following papers: Wilder D. Bancroft, Ph.D., "Constant Voltage and Constant Current Separations;" H. T. Barnes, Ph.D., "Experimental Study of Some Electrode Effects;" J. W. Richards, Ph.D., and W. S. Landis, "The Electrolysis of Water;" Wilder D. Bancroft, Ph.D., "Experiments with Metallic Diaphragms;" C. J. Reed, "Protective Action of Zinc Chloride on Metallic Iron."

At 1 P. M. luncheon will be served at the Chemists' Club, by invitation of the New York members. At 2.30 P. M. reading and discussion of the following papers: Max von Recklinghausen, Ph.D., "Insulating Materials—A Field for Chemists;" H. B. Coho, "A Historical Review of the Storage Battery," with illustrations; Elmer A. Sperry, "The Use of Pyroxyline in Electric Storage Batteries;" W. H. Walker, Ph.D., "The Concentration Changes in the Electrolysis of Brine;" J. W. Walker, Ph.D., "The Influence of Some Impurities in Salt Upon the Yield of Soda by the Amalgam Process;" A. A. Knudson, "The Corrosion of Metals by Electrolysis;" Titus Ulke, "Modern Electrolytic Copper Refining;" N. S. Keith, Ph.D., "A Note on the Composition of Electroplating Solutions;" C. W. Volney, Ph.D., "The Formation of Nitric Acid Under Electric Influences."

At 7 P. M., reception of members and guests in the clubhouse parlors of the German Liederkranz, 111-119 East Fifty-eighth street. At 8 P. M., subscription banquet for members and guests. Ladies are especially invited to participate. The price per cover is $5. A fine musical programme has been arranged.

Friday morning, April 17th, 9.30 A. M., announcement of the results of the election of officers for 1903. Reading and discussion of the following papers: W. D. Bancroft, Ph.D., "Note on Electrical Endosmose;" Louis A. Parsons, Ph.D., "Ions and Electrons;" Carl Hering, "Uniformity in Electrochemical Equivalent;" W. D. Bancroft, Ph.D., "The Electromotive Force of Alloys;" Prof. C. F. Burgess and Carl Hambuechen, Ph.D., "Electrolytic Production of Metallic Compounds;" J. G. Zimmermann, "The Electrodeposition of Metals Upon a Rotating Cathode."

At 1 P. M. luncheon will be served at the Chemists' Club, by invitation of the New York members.

At 2 P. M., excursions to plants and places of interest, as arranged by the Excursion Committee, starting from the Chemists' Club, where detailed notices will be posted.

At 8.30 P. M. the Society will, by special invitation, be the guests of the American Institute of Electrical Engineers at their extra meeting, held in the assembly hall of the Chemists' Club, at which the programme is as follows: President Scott, "Introduction;" W. J. Hammer, "Radium and Other Radioactive Substances, and Certain Phosphorescent and Fluorescent Substances." "The Properties and Applications of Selerium," "The Treatment of Disease by Ultraviolet Rays."

On Saturday morning, April 18th, 9.30 A. M., the following papers will be read and discussed: A. B. Marvin, "Electrolytic Conduction Without Electrodes;" P. G. Salom, "A New Type of Electrolytic Cell;" H. E. Patten and W. R. Alott, "Potentials of Zinc in Aqueous Solutions;" Woolsey McA. Johnson, "Notes on Electrolytic Depositions of Nickel;" Alfred H. Cowles, "What is the Capacity of Molecules for Electric Charge in Electrolysis?" J. A. Steinmetz, "Exhibit of Aluminium Corrosion;" August Eimer, "Exhibit of New Apparatus."

At 1 P. M. luncheon will be served at the Chemists' Club, by invitation of the New York members.

At 2 P. M. excursions will be undertaken to plants and places of interest, as arranged by the Excursion Committee, starting from the Chemists' Club, details of which will be posted.

At 8.30 P. M., meeting in the Chemists' Club, Assembly Hall. Presidential address by President J. W. Richards, Ph.D.; Max von Recklinghausen, Ph.D., Demonstration of the Cooper-Hewitt lamp and rectifier.

At 10 P. M. a German-American smoker (Kneipe) will be held at the Chemists' Club, Assembly Hall, buffet, luncheon, refreshments by courtesy of the New York members. A jolly social evening is assured.

Transportation will be on the certificate plan. All members not residing in New York City should secure certificates when purchasing tickets, in order to get return at one-third rate.

The hotel headquarters of the Society during the convention will be at the Wellington, Seventh avenue and Fifty-fifth street, half a block from the Chemists' Club.

The local committee consists of the following members: Dr. C. A. Doremus, chairman; Alvis von Isakovics, secretary; W. S. Cameron, assistant secretary; G. C. Adams, C. Batchelor, C. S. Bradley, Wm. Hand Browne, Jr., Dr. C. F. Chandler, E. A. Colby, Dr. F. B. Crocker, Dr. G. Drobezy, R. A. Fliess, Dr. H. Foerster-ling, J. C. Hatzel, Dr. N. S. Keith, E. C. Klipstein, A. A. Knudson, Dr. Morris Loeb, W. N. McCoy, C. O. Mailloux, A. Monell, E. H. Mullin, H. N. Potter, Dr. M. von Recklinghausen, E. E. Ries, Dr. S. Sheldon, N. Tesla, W. D. Weaver, E. Weston, C. E. Whitney and Dr. F. G. Wiechmann.

The above elaborate programme shows that the local committee has spared no efforts to insure a full success of the meeting. The attendance promises to be even greater than at the Philadelphia and Niagara Falls meetings.

We are informed that Dr. Walter Nernst, the distinguished professor of electrochemistry at the University of Goettingen, Germany, is expected to be present at the New York meeting.

---

## INTERNATIONAL CONGRESS FOR APPLIED CHEMISTRY.

As already noticed in these columns, the Fifth International Congress for Applied Chemistry will be held in Berlin, June 2 to 8, 1903. Section X is devoted to electrochemistry and physical chemistry.

The American committee for this section, as appointed by President Remsen, of the American Chemical Society, consists of Dr. C. A. Doremus, chairman, and Dr. W. D. Bancroft, Dr. C. F. Chandler, Dr. A. A. Noyes and Dr. Edgar F. Smith.

The fee for membership of the Congress is $4.85, and should be forwarded to Dr. H. W. Wiley, chief of the Bureau of Chemistry, Department of Agriculture, Washington, D. C. Members of the Congress are entitled to receive the full printed proceedings of the Congress.

## NOTES ON A CLASSIFICATION OF ELECTROCHEMISTRY.

By Clinton Paul Townsend

### (I) Introduction.

As an art, electrochemistry is remarkable for the wide range of its applications and for its recent rapid growth. To one desirous of keeping abreast of the progress made, and of having at hand a key to the literature of the subject, the question of its classification is a very important one. The classification outlined below deals exclusively with the "art;" that is to say, with the technical applications of the subject, disregarding all matters appertaining solely to the theory. The subject-matter of batteries or electrochemical generators is also excluded, since no useful purpose seems to be served by including this sharply defined and highly complex art under the general title.

The classification was developed, or rather was permitted to develop, during several years, while the writer was serving as examiner of the class of electrochemistry in the United States Patent Office, and in this capacity was mainly engaged in searching and abstracting the literature and the patents with reference to the question of novelty of applications filed. The system is properly referred to as having been permitted to develop for the reason that no effort was made to deliberately subdivide the art into mutually exclusive classes, into which all applications and literature references should be fitted. Such course would obviously be futile, for inventors and writers alike refuse to limit their efforts to the matters so included, but most persistently deal with subject-matter which is essentially marginal, thereby obliterating such divisional lines as may have been established. The course adopted was therefore to segregate from the main subject-matter certain definite classes, made by the inventors and workers themselves, and the limits of which they have shown no tendency to transgress. The classes so divided from the general subject-matter may be clearly kept, and the material not falling clearly into any of them is left to constitute a part of the "general art." From this residual general art it will be found that additional classes segregate in the most natural manner, as the attention of chemists is directed to one or another portion of the field. So, also, as the classes already formed become complex from the number and variety of references contained in them, it is found advisable to divide out as sub-classes the minor subjects wherein especial activity is displayed.

As stated above, matters relating solely to theory are disregarded, but this statement is to be understood as purely relative; for what is pure theory at one stage of the development may be closely related to and interwoven with the technics of a later stage. While the theory is disregarded in the classification proper, it remains as a part of the "general art," to be carried into the appropriate classes as its bearing upon technical progress is made clear. Many instances of this will appear in the following discussion of the classes.

The classification in general outline is essentially, but not exclusively, functional; that is to say, it is based upon methods of work rather than upon apparatus employed. In its subordinate divisions, however, the basis of classification is quite generally the article, compound or element to be produced.

No attempt is made to so define "electrochemistry" as to place any restriction upon the subject matter included. Whatever falls within the limits of the sub-classes is obviously a portion of the art, and whatever bears thereon or possesses any analogy thereto may properly be included in the indices. The classification should be given the utmost elasticity.

The necessities of cross referencing will, in general, be quite apparent. Such classes as "alternating current electrolysis," "colloidal metals" and "organic non-electrolytes in plating" consist largely of cross references taken from the plating classes, and methods of general utility, but specific application, may conveniently be placed under the sub-classes and cross referenced to the general class. As an instance of the latter, an author describes a method for determining the hardness of electrodeposited chromium. The data secured relate to chromium, and are properly included therewith, but the method, being equally applicable to all metallic deposits, is best classed under "aqueous bath."

No claim is made that the outline classification hereinafter given is the best; merely that it has proven in use to be convenient and elastic. The excellent service done for chemists in this country along bibliographical lines will undoubtedly be repeated in the near future for electrochemistry. In fact, several abstract bibliographies of special classes have already appeared. Meantime, however, the necessity devolves upon each electrochemist of arranging such material as he may have at hand in a manner permitting ready reference, and the suggestions here given are offered to this end.

### (II) Classification Outline.

- Electrochemistry.
  - General art.
  - Alternating-current electrolysis.
  - Aqueous bath.
    - Alloys.
    - Aluminium.
      - Deposition on.
    - Anodes.
      - Oxide coatings.
    - Apparatus.
    - Cathodes.
      - Metallizing.
        - Porous substances.
    - Chromium.
    - Colloidal metals.
    - Compounds.
      - Inorganic.
      - Organic.
        - Oxidation methods.
        - Reduction methods.
    - Copper.
    - Osmose.
    - Gold.
    - Haloids.
      - Bleaching and disinfecting liquors.
      - Chlorates.
      - Mercury cathode.
      - Treating cathode lyes.
    - Hydrogen and oxygen.
    - Iron.
    - Lead.
    - Nickel and cobalt
    - Ores.
      - Gold and silver.
        - Cyanides.
        - Halogens.
      - Zinc.
    - Organic non electrolytes in plating.
    - Pickling
    - Pigments.
      - White lead.
    - Platinum and palladium.
    - Reduction by couple.
    - Refining metals
      - Copper.
      - Nickel.
      - Regenerating electrolyte.
    - Silver.
    - Sulphates.
    - Tin.
      - Treating tin scrap.
    - Zinc.
  - Asymmetric conductors.
  - Carbon.

Depolarizing.
Diaphragms.
Electric furnaces.
Electric-furnace processes.
Carbides.
Calcium.
Cyanides and nitrides.
Diamonds.
Graphite.
Oxides.
Phosphorus and phosphides.
Reduction to metal by carbon.
Silicon and silicides.
Sulphides.
Fused bath.
Aluminium.
Sodium.
Magnetism—electrolysis influenced by
Ozone.
Printing processes.
Purifying liquids.
Alcoholic.
Sugar solutions.
Solid electrolytes.
Solvents other than water.
Synthesis.
Oxides of nitrogen.
Tanning.
Vacuum deposits.

(III) NOTES ON OUTLINE.

*General Art.*—This comprises the material not segregated into the classes which follow. It may not inaptly be likened to the complex mother liquor remaining after a series of separations. Discussion of its composition and the relation of residual matter which it contains to the matter separated is best deferred until after the consideration of the several classes.

*Alternating-current Electrolysis.*—This comprises all electrolytic methods based upon the use of an alternating current, irrespective of purpose or conditions. Purely thermal methods are, of course, excluded. The electrolytic alternating-current meters, measuring alternating currents by the loss of weight of electrodes in cells in shunt or induced circuits, are properly classified here, as are also such wave-registering devices as that of Janet. Other examples are the investigations of Sheldon and Waterman upon the sulphating of lead plates, and those of Roepper and Richards upon the production of insoluble sulphides. The synthesis of various organic compounds, pyrocatechin, hydroquinone and urea, fall under this class, as do also the investigations of Maneuvrier and Chappius on the decomposition of water and those of Gerdes and others on the attack of platinum electrodes in ammonium carbonate solutions. The observations of Burgess on the effect of alternating currents superposed upon direct currents in plating operations relate particularly to nickel, and should be classed with this metal, but are properly cross referenced into the present class. These examples and those which follow are not to be considered in any sense as a summary of the contents of the classes. Such summaries, for certain classes possessing particular interest or exhibiting especial activity, it is hoped to offer later. The present effort is rather to illustrate, by means of examples as diverse as possible, the limits of each class. It will be noted that all of the examples given refer to operations conducted in aqueous solution. This limitation is not imposed by the character of the class, but rather by the fact that investigations have not extended to the wider field.

*Aqueous Bath.*—It is partly an accident of development that renders this the most thoroughly studied and fully subdivided of the general classes, and the extent and character of the subdivisions will illustrate how completely the early growth of the art was associated with the study of salts in solution in water. The broad class of aqueous bath as here retained is distinctly *residual*, occupying precisely the position with reference to its sub-classes that the general art does to the art as a whole. The material classified therein is therefore such as is excluded from the sub-classes immediately following. In general, this may be said to comprise (1) data as to the separation of metals whose electrolytic production has not yet become of such technical importance as to warrant their separate classification, or with reference to which investigations hitherto published have touched only the analytical, as distinguished from the industrial side; (2) articles of broader bearing than the limits of any sub-class, typical examples of which are the papers upon the alloying of metals as a factor in electroplating and on the physical character of metal deposits in a recent issue of the ELECTROCHEMICAL INDUSTRY. Other examples are the work of Jordis on the influence of lactic and glycollic acids on the electrodeposition of metals, the abundant literature on the influence of pressure, temperature, etc., upon deposition, and in general any discussion of factors which have a similar or analogous effect in the deposition of more than a single metal; (3) phenomena not related to the plating operation, such, for instance, as the disintegration of metallic cathodes under high current densities and the electrolysis of salts, not otherwise classified, which yield no metallic ion, the idea being to confine the sub-classes designated by the names of metals to plating operations wherein these metals are separated, as metals or as oxides, at one or the other electrode.

FIG. 1.—1,200-AMPERE SWITCH.

Aqueous bath; alloys. The direct deposition of alloys from solutions of mixed electrolytes.

Aqueous bath; aluminium. The deposition of aluminium from aqueous solutions. This sub-class occupies an anomalous position, possessing the extended and confident literature, but being apparently quite innocent of practical achievement.

Aqueous bath; aluminium, deposition on. The peculiar surface of the metal necessitates particular methods of treatment for the formation of adherent deposits of other metals. This sub-class gives evidence of especial activity and substantial recent progress.

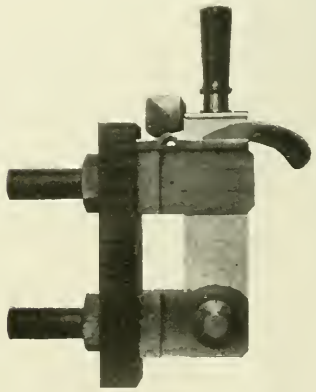

FIG. 2.—1,200-AMPERE SWITCH, WITH SECONDARY ARCING TIP.

Aqueous bath; anodes. The use of an anode is, of course,

common to all methods. This sub-class relates to anode design; their protection at the immersion line; special devices for insuring even current distribution; particular compositions and modes of treatment, and data regarding the life of anodes under specific conditions. The sub-class includes both polarizable and non-polarizable anodes.

Aqueous bath; anodes, oxide coatings. A compact and interesting class, relating mostly to coloring or "browning" iron and steel and the electrolytic imitation of the Russia effect in iron. The separation of metals, as peroxides for analytical and other purposes, not related to the treatment of the anode, is referred to the plating classes.

*(To be continued.)*

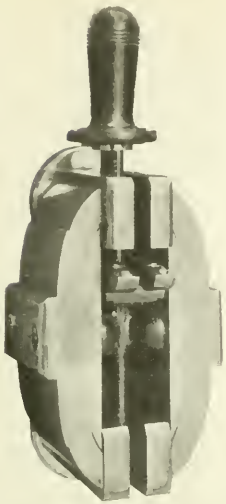

FIG. 3.—3,000 AMPERE 250 VOLT LAMINATED LEVER SWITCH.

## LARGE CAPACITY SWITCHES FOR USE IN ELECTROLYTIC WORK.

By E. M. HEWLETT.

In electrolytic work there are two general methods of connection, the series and the multiple connections. The multiple method of connection necessitates low potential and large current carrying switches, while the series method reduces the current capacity and increases the potential.

The series method is preferable where it is possible, on account of the saving in size of copper conductors and switches. However, in cases where it is necessary to use the lower potentials and large currents, a switch of large capacity and low-contact resistance is required.

FIG. 4.—3,000-AMPERE 250-VOLT LAMINATED LEVER SWITCH.

Considering first the smaller capacity switches, up to 2,000 amperes, the lever type of switch, shown in Figs. 1 and 2, are generally used. These switches are made up with single blades in the smaller capacities, and in the large capacities with two or more blades in parallel. Fig. 2 shows this type of switch with a secondary arcing tip, which is intended to be used where the potential or the character of the load is such as to cause burning at the contacts.

The design is simple, in construction rugged, making a very serviceable switch. Considerable effort is required to operate this type of switch in capacities above 2,000 amperes.

For capacities above 2,000 amperes, and up to 4,000 amperes, the laminated lever type of switch lends itself better, on account of requiring less effort to operate and insuring good contact.

This switch is shown in Figs. 3 and 4, and is made up of a pair of bridging laminated contacts, embracing either side of the contact stud; and the design is such as to insure each individual lamination making separate and positive contact on the stud, thus making an excellent contact of very low resistance.

FIG. 5.—8,000 AMPERE SWITCH.

The laminated lever switches are fitted with secondary arcing tips to take the final break, consequently preventing all roughing of the main contacts due to the arc. These switches are made single, double and triple-pole, single and double throw, and are made in capacities from 1,200 to 4,000 amperes.

In order to make a switch which would operate more easily in larger capacities, the laminated toggle brush switch was designed, as shown in Figs. 5 and 6.

This type of switch is more easily operated for a given capacity than any other, the contacts being of the laminated bridge type and forced in contact under pressure by a toggle. The laminated type of contact is particularly effectual on account of the characteristic of individual contact of the

FIG. 6.—8,000 AMPERE SWITCH.

separate laminations. To insure this positive individual contact it requires a great amount of pressure. The toggle construction makes it possible to obtain this pressure with a minimum effort.

This switch is made in capacities from 2,000 to 12,000 amperes, is fitted with a secondary arcing tip, which protects the main contacts from the effect of the arc on rupturing, and is made single-pole, single, double and triple-throw.

## NOTES ON THE HISTORY OF ELECTROLYTIC COPPER REFINING IN AMERICA.

By Titus Ulke.

In 1879 an experimental plant for refining copper by electrolysis was operated for a short time at Phœnixville, Pa., but the first commercial refinery in America was built by Edward Balbach & Sons at Newark, N. J., early in the 80's.

Up to about 1882 the precious metals were extracted from copper bullion in the United States by the sulphate of copper or vitriolisation process chiefly. With increasing supplies, however, the production very soon exceeded the consumption of sulphate of copper, and the necessity of utilizing another process became more and more obvious. This led to a trial of the electric current for effecting the separation by Messrs. Balbach at Newark, although a previous attempt in this direction, made at Baltimore, had turned out a failure and served as a warning against repetition.

Mr. Balbach, Sr., an excellent practical chemist, and his able son, Mr. Ed. Balbach, Jr., now president of the Balbach Smelting and Refining Co., entrusted Mr. F. A. Thum, a mining and metallurgical engineer, with the task of conducting the experimental work of the new process. The trials proving successful, an electrolytic refinery was erected in 1882-1883 and placed in charge of Mr. Thum, who still ably fills the position of its superintendent.

As it is with almost every case of pioneer work, the difficulties to overcome were many, and discouraging results were frequent at the experimental stage of the process. Under these circumstances, Messrs. Balbach certainly deserve much credit for not relaxing their efforts in continuing the comparatively expensive trials. Owing to the secrecy maintained by English and German refiners, it was next to impossible to obtain working data from them; nor did the patents of James Elkington, the father of electrolytic copper refining, disclose the desired information.

Upon Mr. Thum, therefore, devolved the task of working out the details, such as determining the proper energy of the current required per vat, the arrangement and size of the tanks and of the copper conductors, the way of suspending the electrodes, the production and preparation of the starting sheets and the composition and correction of the electrolyte. As a matter of fact, the rules established and appliances devised by Mr. Thum form the basis of the refining process now in general use, and have been adopted by nearly all American electrolytic copper works.

In those early days there were no voltmeters or ammeters on the market, it appears, and they had to be constructed by each experimenter under the then existing conditions. Apparatus based on the fact that the current from one Daniell cell had a sufficient voltage to drive it through three or four sulphate vats, according to the acidity and temperature of the electrolyte, and that the quantity of the copper deposited in a given time varied directly as the area of the electrodes, and could be increased up to the point where the current-furnishing dynamo began to overheat, at the start served as excellent guides.

The first dynamos used by Messrs. Balbach were furnished by the Excelsior Electrical Co., who were represented by Mr. Wm. Hochhausen, who also assisted in working out the process.

The problem of how to suspend the electrodes and make as perfect a contact with the conductors as possible, while reducing to a minimum the distance between electrodes and allowing the electrolyte to circulate freely, was satisfactorily solved by Mr. Thum by giving the anodes side lugs and their present shape and bending the cathodes over U-shaped suspension bars. At the same time the formula for the proper composition of the electrolyte and a quick and effective way of regenerating it, both of which are in general use to-day, was discovered. Thus, by the end of 1883, all the chief technical points in electrolytic copper refining were satisfactorily settled. The Balbach works, even at that early date, produced from 2 to 3 tons of electrolytic copper daily, but, as this production was soon considered inadequate, they were remodeled until they reached their present tonnage and high state of efficiency.

The refineries at Baltimore, Md., and at Anaconda and Great Falls, Mont., were not started until 1887, 1891 and 1892, respectively. In 1895 the Guggenheim refinery, now known as the Perth Amboy plant of the American Smelting and Refining Co., was built, and in 1898 ground was broken for the erection of the great Raritan Copper Works, Perth Amboy, N. J., and the current turned on in the tank house March 23, 1899, after an interval of less than eight months.

The 50-ton De Lamar electrolytic works were started March 14, 1902, and the new 100-ton tank house and equipment at the Perth Amboy plant (Guggenheim works), arranged according to A. L. Walker's improved design, were put in commission last year.

Sixteen years ago the Balbach and the Bridgeport, Conn., works were the only large electrolytic plants in America, and their output was less than 24 short tons of copper per diem. Yet to-day there are in operation ten electrolytic refineries, producing the enormous quantity of 705 tons daily, or about 257,000 tons of copper annually, besides over 25,000,000 ounces of silver and 318,000 ounces of gold.

## REDUCTION FACTORS FOR ELECTROLYTIC DEPOSITS.

By Carl Hering.

As there are quite a number of different units or quantities in terms of which the amounts of substances reduced or formed electrolytically are expressed, it often becomes necessary or desirable to change from one unit to another. While many of these reductions from one to the other are comparatively simple, yet they always involve some labor and introduce the possibility of making an error. To avoid this, and to show at a glance what relations the units bear to one another, the following table of reduction factors has been calculated under the direction of the writer, and will often be found to be quite useful.

The table gives the value of each unit in terms of each of the others into which it is likely to be converted, so that in any case only one multiplication is necessary. Moreover, the reciprocal values are also given in most cases in their proper places, thus avoiding all long divisions. Approximate values have also been added, which are correct within 2 per cent., and are therefore sufficiently accurate for most practical purposes. These approximate numbers have been so chosen that they involve the least possible figuring, generally only a multiplication by a single digit, a division by another and sometimes the pointing off of some decimal places. This requires even less figuring than a multiplication by a value given in only two figures, which involves three rows of figures and an addition. Moreover, the error in using only two-figure values is variable, and may be as high as 10 per cent., while with these approximate values it is always within 2 per cent.

The figures are not a compilation, but have all been re-calculated from the legal weights and measures of this country (and with a very slight difference of Great Britain also), as used by the National Bureau of Standards in Washington. They have been carefully calculated and subsequently checked, and it is believed there are no errors. They are given in the order of

size. The year in the larger commercial units was taken as 365¼ days.

It will be noticed that there are a number of unsuspectedly simple and easily-remembered relations between a number of these units. For instance, 5½ pounds per day are almost exactly a ton (of 2,000 pounds) per year, or 5½ kilograms per day are equal to 2 metric tons per year. Every gram per minute is about 3 pounds per day, or nearly 1½ kilograms per day. A ton per year is about 134 grams per minute. A metric ton per year is about 6 pounds per day, or ¼ pound per hour. Other similar relations may readily be found from the table:

1 pound (av.) per year *(lb./yr.)* equals:
0.002738 pound per day.—Aprx. 11/4 ÷ 1,000.
0.0008624 gram per minute.—Aprx. 6.7 ÷ 1,000.

1 kilogram per year *(kg./yr.)* equals:
0.006036 pound per day.—Aprx. 6 ÷ 1,000.
0.002738 kilogram per day.—Aprx. 11/4 ÷ 1,000.
0.001901 gram per minute.—Aprx. 19 ÷ 10,000.

1 gram per hour *(g./hr.)* equals:
1/60 or 0.01667 gram per minute, which see for other values.

1 milligram per second *(mg./sec.)* equals:
0.00 gram per minute, which see for other values.

1 pound (av.) per day *(lb./day)* equals:
365.25 pounds per year.—Aprx. 11 3 × 100.
165.7 kilograms per year.—Aprx. 1 6 × 1,000.
2/3 or 0.6667 ounce per hour.
0.4530 kilogram per day.—Aprx. 9 2 ÷ 10.
0.3150 gram per minute.—Aprx. 31 ÷ 100.
0.1826 ton (net) per year.—Aprx. 11 6 ÷ 10.
0.1657 metric ton per year.—Aprx. 1/6.
1/24 or 0.04167 pound per hour.
0.01890 kilogram per hour.—Aprx. 19 ÷ 1,000.

1 ounce (av.) per hour *(oz./hr.)* equals:
3/2 or 1.5 pounds per day.
0.6804 kilogram per day.—Aprx. 68 ÷ 100.
0.4725 gram per minute.—Aprx. 14 3 ÷ 10.

1 kilogram per day *(kg. day)* equals:
805.2 pounds per year.—Aprx. 800.
365.25 kilograms per year.—Aprx. 11 3 × 100
0.6944 gram per minute.—Aprx. 7 10.
0.4026 ton (net) per year.—Aprx. 4 10.
0.36525 metric ton per year.—Aprx. 11 3 ÷ 10.
0.00186 pound per hour.—Aprx. 1/11.
1/24 or 0.04167 kilogram per hour.

1 gram per minute *(gr. min.)* equals:
1159.5 pounds per year.—Aprx. 7 6 × 1,000.
525.96 kilograms per year.—Aprx. 1 19 × 10,000
60 grams per hour.
100/6 or 16.67 milligrams per second.
3.175 pounds per day.—Aprx. 32 10.
1.44 kilograms per day.—Aprx. 10 7.
0.5800 ton (net) per year.—Aprx. 4 7
0.5260 metric ton per year.—Aprx. 10 19
0.1323 pound per hour.—Aprx. 4 3 ÷ 10.
0.06 kilogram per hour.

1 ton (net) per year *(ton yr.)* equals:
5.476 pounds per day.—Aprx. 11 2.
2.484 kilograms per day.—Aprx. 10 4
1.725 grams per minute.—Aprx. 7 4.
0.2282 pound per hour.—Aprx. 9 4 ÷ 10
0.1035 kilogram per hour.—Aprx. 31 3 ÷ 10.

1 metric ton per year *(t. yr.)* equals:
6.030 pounds per day.—Aprx. 6.
2.738 kilograms per day.—Aprx. 3 11 × 10
1.901 grams per minute.—Aprx. 19 10.
0.2515 pound per hour.—Aprx. 1/4.
0.1141 kilogram per hour.—Aprx. 8 7

1 pound (av.) per hour *(lb. hr.)* equals:
8766. pounds per year.—Aprx. 7 8 × 10,000
3970. kilograms per year.—Aprx. 4,000.
10.89 kilograms per day.—Aprx. 11.
7.500 grams per minute.—Aprx. 3 4 × 10.
4.383 tons (net) per year.—Aprx. 4 9 × 10.
3.976 metric tons per year.—Aprx. 4.

1 kilogram per hour *(kg. hr.)* equals:
19,325 pounds per year.—Aprx. 19,000.
8,760 kilograms per year.—Aprx. 7 8 × 10,000.

1 kilogram per hour *(kg. hr.)* equals:
52.91 pounds per day.—Aprx. 53.
100/6 or 16.67 grams per minute.
9.663 tons (net) per year.—Aprx. 29/3 or 3 3/31 × 100.
8.760 metric tons per year.—Aprx. 7 8 × 10.

1 ounce (av.) per minute equals:
3¾ pounds per hour, which see for other values.

---

## EQUIPMENT OF AN ELECTROMETALLURGICAL LABORATORY.*

BY R. S. HUTTON AND J. E. TEAVEL.

In considering the equipment of a laboratory for experimental work in electrometallurgy, the point of utmost importance should be, in the first place, to provide power to enable the experiments to be carried out on a reasonably large scale. The actual magnitude of the power equipment must be regulated by two principles. It is very desirable that the experiments, though not on a scale directly comparable with the commercial process, should nevertheless be of sufficient magnitude to furnish reliable practical data. On the other hand, as the question of cost has, unfortunately, to be considered, it is necessary to keep the equipment within certain limits, so that any given experiment can be repeated frequently under all possible conditions. Such work will supply not only valuable scientific information, but also the necessary data for practical application.

Having said thus much with regard to the scale of the work, let us consider what should be the main points governing the choice of equipment. The variety of different forms of electric furnaces which have been proposed or used is extremely great, and it would be altogether impossible to provide in any laboratory, however large or wealthy, even the most important of these. With regard to the generating plant, the same may be said. In commercial work we find conditions varying from the 15,000-volt nitric acid plant down to the 4 or 5 volts required by the zinc or aluminium processes; from the continuous current used in all electrolytic work to the polyphase alternating current employed in the purely electro thermal reactions.

Our object, therefore, must be not to establish a limited number of definite examples, but to obtain an equipment extremely flexible, so that, without serious expense, any of the conditions required by such work may be obtained. It is, unfortunately, rarely possible to turn an ideal into a concrete fact. The development of a laboratory must necessarily be gradual, each year bringing alterations and improvements. Nevertheless a description of the actual equipment of the electrochemical laboratory of Owens College may be of some value to those interested in the subject, either from a commercial or theoretical point of view. The motive power at present available is rather insufficient, but hopes are entertained that it may before long be increased. It consists of a gas engine and dynamo, which can be coupled onto the same driving shaft, and together are capable of developing a net output of 30 to 40 kw. The generating plant comprises several different types of machines.

One unit of 10 kw is capable of being connected so as to give any electromotive force between 10 and 200 volts, the maximum current being 600 ampères. This dynamo is used for arc fur-

* This is one part of a paper read before the Manchester section of the British Institution of Electrical Engineers. Mr. R. S. Hutton, who visited this country last year and read a paper on the fusion of quartz in the electric furnace at the Niagara Falls meeting of the American Electrochemical Society [Electrochemi al Industry vol. I. p. 58] is in charge of the electrochemical laboratory of Owens College, Manchester. In the other parts of their paper the authors give notes on technical processes, mainly those used at Niagara Falls, which have already been fully discussed in ELECTROCHEMICAL INDUSTRY.—Ed.

[illegible] work. Finally, a dynamo specially intended for electrolytic work, consisting of [illegible] amperes at 15 volts. With regard to alternating currents, a 40-kw three-phase and a 20-kw single-phase motor are provided. The latter can be connected so as to give anything between 30 amperes at 600 volts and 250 amperes at 72 volts. Finally, plant used some time ago by Mr. McDougall for the manufacture of nitric acid was presented by him to the laboratory. It will give alternating current up to 10,000 volts.

Passing now from the dynamo house to the electrochemical laboratory itself, the first problem is the exact regulation of

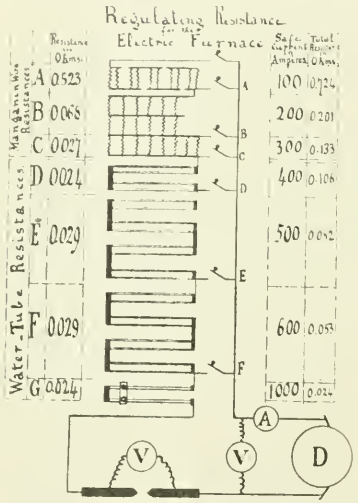

FIG. 1.—REGULATING RESISTANCE FOR ELECTRIC FURNACES.

these comparatively large currents, since, for satisfactorily studying some of the electrolytic processes, it is absolutely essential to have the current entirely under control. The diagram of the series resistance used for this purpose is shown in

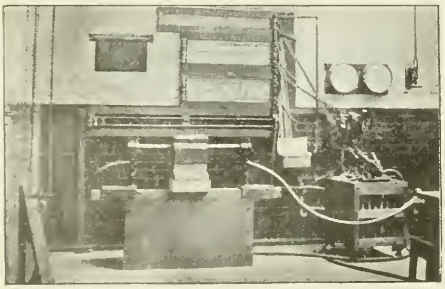

FIG. 2.—REGULATING RESISTANCE FOR 40 KW MOISSAN FURNACE.

Fig. 1. As will be seen, a number of switches are provided, by means of which successive portions may be short-circuited. Frames A, B, C are manganin wire resistances, and, together with the corresponding switches, are mounted on a stand fitted with rollers. The other frames consist of German silver tubes, fixed permanently to the wall and provided with a water circulation. D is made of $\frac{1}{4}$-inch tubes, about 4 feet long and 0.025 inch thick; E and F of $\frac{1}{4}$-inch tubes, 3 feet long and 0.03 inch thick, whilst G is of $\frac{1}{2}$-inch tubes, 6$\frac{1}{2}$ feet long and 0.02 inch thick.

This resistance is divided into two parts, the first of manganin wire, designed particularly for starting an arc furnace, and capable of being used for currents up to 300 ampères; the second consisting of German silver tubes, water cooled, and with maximum carrying capacity of 1,000 ampères. After some consideration, the water-tube resistance was chosen as being the most suitable for regulating large currents,* and, as this subject is of some general interest, we venture to give details of the design and of the behavior under actual working conditions. The design of the water-tube frames is shown in Fig. 2, which gives a general view of the frames, and Figs. 3 and 4 give detail of the design of the terminal pieces. Fig. 2

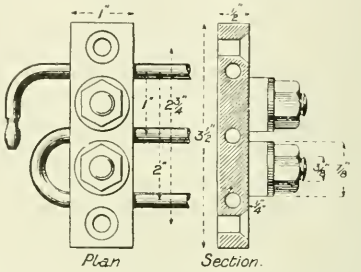

FIG. 3.—TERMINALS OF WATER-TUBE RESISTANCE (600-AMPERE FRAME).

shows the regulating resistance for a 40-kw Moissan furnace. To the right is the portable resistance, and above the 500, 600 and 1,000-ampère short-circulating switches. Bare copper strips, 1$\frac{1}{4}$ x $\frac{1}{4}$ inch and 2 x $\frac{1}{4}$ inch, connect these switches with the different frames seen in the center. The two carbons are carried in massive copper holders, which can be adjusted to any given height, the leads being bolted to the vertical standard of the holder of 2$\frac{1}{4}$ square inches cross section.

The frames are of two types, the first being made of parallel $\frac{1}{4}$-inch tubes for currents of 600 ampères and below. As will be seen, these tubes are let into $\frac{1}{2}$ x 1-inch gun-metal strips, which are fixed onto wooden frames; each strip carries two $\frac{1}{8}$-inch set screws, serving as terminals. One of these is used for the permanent leads, the other is useful to fix any temporary connection. The second type of frame for 1,000 ampères consists of two $\frac{1}{2}$-inch German silver tubes, 6$\frac{1}{2}$ feet long, connected in series, and has a resistance of 0.024 ohm.

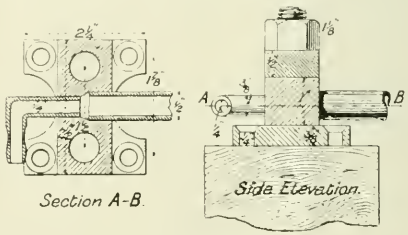

FIG. 4.—TERMINALS OF WATER-TUBE RESISTANCE (1,000-AMPERE FRAME).

The terminals shown in Fig. 4 are similar to those just described, but more massive. Two sliders are provided, of the design shown in Fig. 5, by which the actual resistance in circuit can be varied and the current adjusted with accuracy to the value desired.

As will be seen, there is a stiff central spring, by means of which the sliders are kept in contact with the tubes during adjustment. They can be clamped in any given position by two thumb screws. In considering the maximum power which

* See also *Zeitschr. für Elektrochemie*, vol. 8, p. p. 6, 58, 123, 124 (1902).

may be dissipated in a water tube resistance, we are concerned with two principal factors. Firstly, the maximum rate at which water can be passed through the tubes; secondly, the maximum rate at which heat can be transmitted from the metal to the water. In all practical cases the first limiting factor will intervene long before the second would show its influence. The design of the water-tube frame will therefore depend on the dimensions of the tube and the available head of water. As a general guiding factor, we may say that a flow of 1 liter per minute will dissipate up to $2\frac{1}{2}$ kw.

The larger tubes are distinctly the more satisfactory, since in this case there is no difficulty in obtaining an efficient flow of water from the ordinary supply. With the smaller tubes it

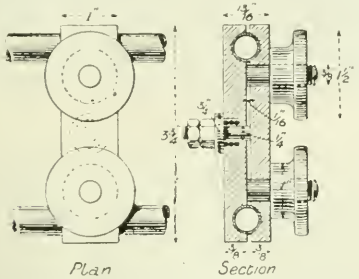

FIG. 5.—SLIDES FOR 1,000-AMPERE WATER-TUBE RESISTANCE.

is necessary to have numerous inlets and outlets, as their resistance to the flow of water is considerable.

Close to the water tubes a resistance is provided by which the exciting current of any of the dynamos can be most effectively regulated. It is in constant use for the considerable variations of voltage necessary during the progress of some of the furnace operations.

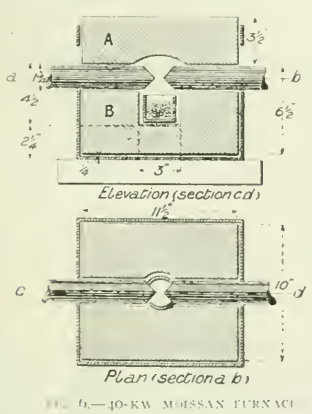

FIG. 6.—40-KW MOISSAN FURNACE.

We now come to the actual furnace equipment and the different types of apparatus which are best adapted for laboratory work. Foremost amongst these must be placed the Moissan furnace.* A dimensioned drawing of this type for a power of about 40 kw is given in Fig. 6.

This is constructed of blocks of Monk's Park bath stone, which, after trials with various limestones, has proved to be the most suitable. The furnace is composed of two blocks, the first, A, forming the cover, the second, B, the furnace proper. This latter has two grooves of slightly greater diameter than the carbons to be used. As the blocks are apt to split under the influence of the heat, they are held together by iron bands. These are provided with sockets (not shown in figure), which enable the furnace or cover to be lifted by long iron bars. The central hole, which may be of diameter $2\frac{1}{2}$ to 4 inches, according to size of crucible in use, is lined at the bottom by a layer of powdered magnesia, which prevents the carbon crucible coming in direct contact with the lime. An annular space should be left around the crucible, which not only facilitates the heating, but also prevents the lime and carbon from entering into combination.

Taking into consideration the many discoveries made by Moissan in the course of his investigations, it is surprising that as yet only a very small percentage have found commercial application. The reason of this may perhaps be ascribed to the fact that this form of furnace, though proving itself eminently suitable for the pioneering work for which it was intended, scarcely gives any data on which a technical process could be founded. It is, in fact, a striking example of how the apparatus most suited for purely scientific work is seldom capable of direct commercial application. It was not until the work was taken up by the practical engineer that the scientific discovery developed into a commercial industry.

Most frequently the financial success of a process has been in direct proportion to the mechanical improvements introduced, the chemical modifications being generally of secondary importance. It is therefore necessary to be able to provide a type of

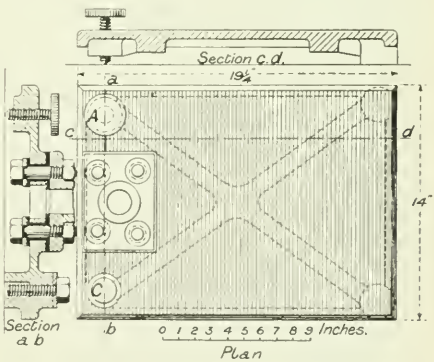

FIG. 7.—VERTICAL ELECTRIC FURNACE PLAN.

furnace corresponding in principle to the most usual technical forms, and thus carry out the experiments; if not on the same scale, at least in the same manner as would be done in the factory. Fig. 7 is a plan of an apparatus similar to that used by Haber,* which we have found extremely useful for representing many different forms of furnace. The apparatus consists of a cast iron base, an adjustable standard and a feeding gear. The base is $\frac{1}{2}$ inch ruling thickness, strengthened with ribs and cross ribs 1 inch thick. At one corner a $\frac{3}{4}$-inch bolt C serves as a terminal. A is a leveling screw. The square base of the standard is insulated by a slab of vulcanized fibre, and held down by four $\frac{3}{4}$-inch bolts. See section A-B.

Fig. 8 is the vertical furnace elevation. A hollow cast-iron column R, $2\frac{1}{2}$ inches diameter, is fixed onto the base shown in the previous figure, but insulated from it. The height of the gun-metal cross bar carrying the screw feeding gear can be adjusted within wide limits by means of the $1\frac{1}{4}$-inch steel rod S, which is clamped in position by the hand wheels A and B. Connection can be made at either of the terminals K or E (the latter for currents above 600 amperes), the opposite pole being connected to the base. To avoid sliding contacts, which would be objectionable for such large currents, connection from the cross bar to the screw carrying the carbon rod is made by means of four $\frac{1}{2}$-inch flexibles, not shown in this figure, but which can be clearly seen in Fig. 9. The gun-metal rod T, which carries the carbon is $1\frac{1}{2}$ inches diameter, with a square

* Moissan, *Le Four Electrique*, Paris, 1897.

* Haber, *Zeitschr. fur Elektrochemie*, vol. 8, pp. 1, 26, 60 (1902).

screw thread (four threads to the inch), giving a feed of about 1 foot. It is raised or lowered by means of a 7-inch cast-iron hand wheel. The design of the carbon holder is clearly shown. It is provided with rings of various diameter,

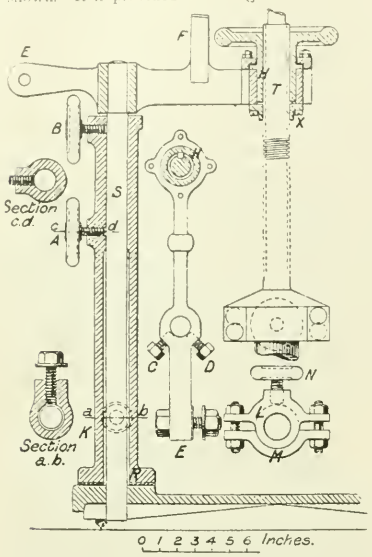

FIG. 8.—VERTICAL ELECTRIC FURNACE ELEVATION.

so that carbons of very different sizes up to 3 inches can be held.

Fig. 9, A, shows one way in which the vertical furnace, the design of which is shown in the previous figures, can be used. Upon the cast-iron base which forms the negative pole is

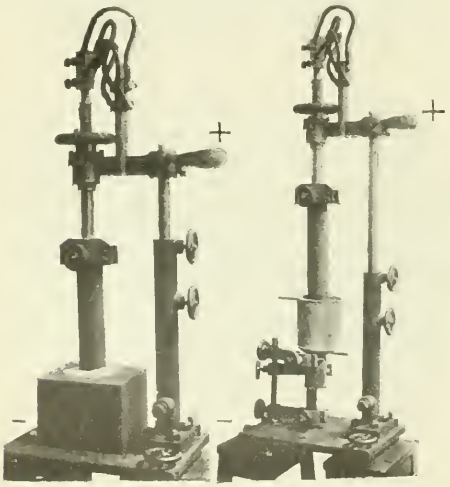

FIG. 9A. ELECTRIC FURNACES. FIG. 9B.

placed a large block of carbon, having a cavity which serves as a crucible. The positive electrode is formed by a carbon 3 inches in diameter, which is fed by the screw gear described above.

In Fig. 9, B, the apparatus is fitted to be used for the electrolysis of fused salts. The water jacket, by causing a layer of the fused mass to solidify, enables the electrolyte itself to form the crucible lining. This is frequently necessary, since

FIG. 10.—40 HP. CARBORUNDUM FURNACE.

with many substances it is impossible to find a furnace material capable of withstanding their corrosive action at the high

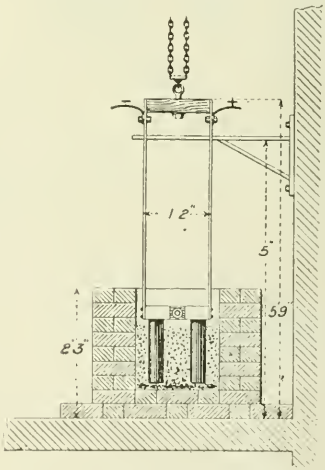

FIG. 11.—40 KW EXPERIMENTAL CARBIDE FURNACE.

temperatures which prevail. The negative pole is in this case formed by a vertical carbon, which is held in a clamp sliding on a gun-metal vertical rod fixed to the base.

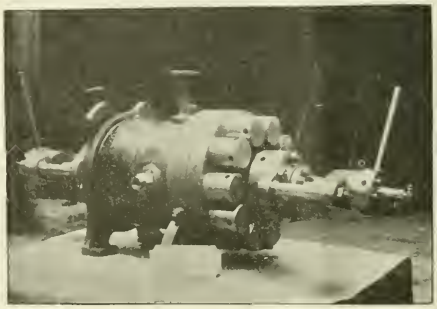

FIG. 12.—HIGH PRESSURE APPARATUS.

Connected as shown in Fig. 9, A, the furnace has proved

itself most satisfactory for the manufacture of aluminium by the electrolysis of cryolite containing $Al_2O_3$. Replacing the carbon block shown in this figure by a small furnace built of loose bricks, a good example of a carbide "pot" furnace, giving a most satisfactory yield of calcium carbide, can be obtained. Frequently in the electrolysis of fused salts it is an absolute necessity to make the crucible lining of the material itself. This result is obtained (as shown by Muthmann, Hofer and Weiss)* by the use of a water-cooled crucible. The arrangement is shown in Fig. 9, B. Whilst the vertical holder enables us to represent a large number of different types of furnace, those of the Acheson carborundum type can be very simply built up by the use of ordinary materials.

Fig. 10 shows a carborundum furnace as used with 40 hp. This is an almost exact reproduction of the commercial furnace on a small scale. It is built up of loose fire bricks on a cast iron base, the outside dimensions being 46 inches long, 28 inches broad and 21 inches high. The electrodes, consisting each of two graphite plates, $2^1/_2 \times 1$ inch, are in contact with coke, which also forms the core connecting the two. This is a resistance furnace of type E, shown in Fig. 13. The core is surrounded by the mixture of sand, coke, sawdust and salt, from which the carborundum is made.

The next figure (Fig. 11) is a drawing of a furnace suitable for making calcium carbide or for other furnace operations. The design is inexpensive, and the apparatus most serviceable. It represents a satisfactory and convenient laboratory form of many and important technical furnaces. The two carbons, which are clamped side by side in a single holder, but insulated one from another, are raised and lowered by means of a crane fitted to the wall. The current is led in by flat copper bars, which, by sliding in grooves, prevent any oscillation or side motion of the apparatus. The body of the furnace consists either, as shown in the figure, of fire bricks or of a large cast-iron pot. In both cases the material itself forms the actual lining.

* *Liebig's Annalen*,—vol. 320, pp. 231—269 (1902).

Such experimental equipment will be of importance not only from an educational point of view, but it is by no means impossible that certain of the difficulties in technical processes may be overcome by its use.

It is important, however, not to neglect the purely scientific work, which, though it may possibly not find any direct application in the immediate future, has, however, frequently proved to be the starting point of notable advances. In this direction the work in progress consists in the determination of the effect of gaseous pressure on high-temperature chemical phenomena. It is proposed to study carefully some of the gaseous and other reactions, which may be expected to differ considerably from those occurring under ordinary conditions.

The apparatus shown in Fig. 12 is destined for work up to 200 atmospheres and for currents up to 1,000 amperes, and has been provided out of funds received from the Government Grant Committee of the Royal Society. The apparatus is practically a steel inclosure, placed either horizontally or vertically, which can be used for any of the different types of furnace. It is air-tight, and designed for a working pressure of 200 atmospheres, being tested at 500 atmospheres. On the right and left will be seen the screw gear by which the carbons are fed, whilst in front and behind are windows which will stand the full pressure, but which can be replaced by additional connections when a circulation of gas through the apparatus is desired. The main valve, which serves also to connect the pressure gauges, will be seen on the top. The apparatus is water-jacketed throughout, the refractory material of which the furnace proper is made being contained in a cast-iron lining, thus insuring the protection of the main forging. The construction of this apparatus has been carried out by Messrs. Lennox, Reynolds and Fyfe to the designs made at the college.

## SOLID ELECTROLYTE CELLS.

By A. L. Marsh.

Previous to the year 1885 there had not been made a voltaic cell with a solid electrolyte which, at ordinary temperatures, could generate even the smallest appreciable electric current. Sir William Thomson, now Lord Kelvin, found that when warm glass was placed between plates of zinc and copper an electromotive force was indicated by an electrometer connected with the metals. Professors Ayrton and Perry extended the observation to the cases of paraffine wax, gutta percha, india rubber and shellac. But with electrolytes of such high resistance no current could possibly be generated of sufficient strength to be indicated by the most delicate galvanometer.

On June 27, 1885, Shelford Bidwell exhibited to the Physical Society a cell with plates of silver and copper, and having for electrolyte a mixture of one part of copper sulphide (CuS) with five parts of sulphur. When connected with a reflecting galvanometer, this cell produced a current which moved the spot of light off the scale.

The electromotive force of the cell was found to be .07 volt, and the internal resistance 6.537 ohms. Upon attempting to reduce this resistance by diminishing the proportion of free sulphur, the electromotive force gradually diminished as the proportion of sulphur was decreased, until the voltage became 0, when only copper sulphide was present—at least no appreciable current was given. Copper was the positive pole of this cell.

Bidwell reasoned that the sulphur owed its efficiency to the fact that silver sulphide is formed on the silver plate by direct combination. He therefore constructed the following cell: A thin layer of copper sulphide was spread upon a copper plate and compressed into a compact mass against a surface of polished steel. A layer of silver sulphide was then spread upon the copper sulphide, and the cell was completed by pressing a plate of silver upon the silver sulphide. The current which this cell produced through the shunted galvanometer was considerably greater than that from the cell first described.

The cell was still not satisfactory. There seemed to be indications of short-circuiting, which Bidwell thought might be due to the penetration of particles of copper sulphide through the layer of silver sulphide. The silver plate was removed from the cell, and its surface brushed over with a dilute solution of sulphur in bisulphide of carbon. The plate was then heated over a gas flame, and was soon covered with a uniform and continuous layer of silver sulphide, the heating being continued until all the free sulphur was volatilized. The cell constructed with this prepared plate produced a current of 6,800 microampères through an external resistance of .2 ohm, and was able to deflect the pivoted needle of an ordinary galvanometer. The dimensions of the cell were as follows: The plates were 2 x 2½ inches; the thickness of the two layers of strongly-compressed sulphides was about one-twentieth of an inch. The electromotive force was .053 volt. The internal resistance was therefore about 7 ohms.

Carhart's "Primary Batteries" and Benjamin's "Voltaic Cell" give a brief description of the above cell. They state the electromotive force to be .5 volt, which is evidently a mistake. The correct value is .05 volt.

This cell seems to be exactly analogous to the Daniell cell.

Copper, copper sulphide, silver sulphide, silver (Bidwell cell).

Copper, copper sulphate, zinc sulphate, zinc (Daniell cell).

Bidwell adds that silver is probably the best (or only) possible metal for the positive plate.

Later Bidwell constructed a cell of lead and metallic sodium for the two plates, with lead peroxide for the electrolyte. This combination gave a very powerful current. No figures were given.

The writer undertook a brief study of solid electrolyte cells in the spring of 1900. The first experiments were a repetition of those of Shelford Bidwell with the sulphides of silver and copper, and gave results closely agreeing with those obtained by Bidwell as to the electromotive force produced in each case. The measurements were made with a reflecting galvanometer and condenser. The following combinations were then tried:

Copper, mixture of copper phosphide and red phosphorus, zinc.

Copper, mixture of copper phosphide and red phosphorus, sodium.

Copper, arsenic (metallic), sodium.

The copper phosphide was prepared by mixing pure sponge copper, obtained by electrolysis of a copper sulphate solution, with red phosphorus in the proper proportion to form the compound $Cu_3P_2$. The mixture was slowly heated in absence of air until combination took place, which is indicated by a slight explosion. By washing this product with a dilute solution of potassium bichromate, to which a little sulphuric acid is added, and afterward with distilled water, a procedure recommended by Boettger, a quite pure product of copper phosphide ($Cu_3P_2$) is obtained.

For one set of experiments, a mixture of coper phosphide and red phosphorus was taken for the electrolyte, and compressed between a piece of metallic sodium and a sheet of copper, and the whole kept under a light oil. The electromotive force was found to be about 1.5 volts, and the resistance was less than 100 ohms per square inch of contact surface. The electromotive force did not materially increase when the percentage of phosphorus in the mixture was increased to about 75 per cent., but the resistance became much greater.

By substituting zinc for the metallic sodium in the above combination, the electromotive force of the couple becomes about .8 volt. A cell prepared in a glass tube three-eighths of an inch in diameter gave a sufficiently strong current to move the mercury column of a not very delicate Lippman electrometer.

The arrangement of the cell is shown in the figure. The zinc is used in the form of an amalgam, of such a consistency that it can be poured into the cell when hot and cools to a rather solid paste. The mixture of copper phosphide and phosphorus is pressed in over the zinc amalgam, and a disk of copper is pressed firmly over the mixture. The connection to the zinc amalgam was made by a platinum wire, which was sealed into the glass. The materials used were carefully dried before putting into the cell, and the completed cell kept in a desiccator over sulphuric acid.

The following experiment was tried: A small lump of metallic arsenic was pressed against a slab of sodium, and the whole covered with a light oil. Each metal had a thin copper wire connected to it. An electromotive force of 1.2 volts was shown by a potentiometer. On another trial a copper-arsenic-sodium couple gave at the start an electromotive force of .05 volt. The cell was allowed to stand on closed circuit with 1,000 ohms external resistance. The electromotive force steadily increased, and at the end of ten days had reached .3 volt.

It is a difficult matter to get the materials absolutely free from water, but, granting that in the experiments described above there was a trace of water present, we should hardly expect the comparatively low resistance shown by solid electrolyte cells to be due to the pressure of water, since the materials are practically insoluble in water. However, the small number of experiments performed does not admit of any positive conclusions being drawn.

This class of cells has so far been but little studied, but it is to be hoped that the importance of these cells, from a scientific point of view, will induce others to take up their study. The work of the writer along this line was cut short, and facilities for its continuance are not yet available.

Owing to their rather high resistance, solid electrolyte cells will probably find little practical use. It is possible that they may be used as standards of electromotive force, but so little has been done in the study of this type of cell that their adaptability to this work is uncertain.

## STEEL PRODUCTION IN THE ELECTRIC FURNACE.

Dr. Goldschmidt, the well-known inventor of the Goldschmidt process, last year received a commission from the German Patent Office to go to Italy and investigate a Stassano electric furnace which was in practical operation, in order to ascertain whether it was really possible to manufacture iron in this furnace, containing less than .2 per cent. of carbon. He had occasion, during several days, to study the process in detail, and to take samples of the raw materials and finished products for analysis. The following is an abstract from a paper about the process, read by him before a recent meeting of the Electrochemical Society of Cologne.

The plant is situated at Darfs, to the north of the dago d'Tseo. The most essential feature of the Stassano process consists in the direct reduction of the iron ores by charcoal, in combination with the heat radiated by an electric arc working above the charge. At the same time undesired compounds in the ore are slagged off by means of suitable fluxes. Large carbon rods are introduced from opposite sides into a shaft furnace, constructed of masonry, with a working chamber 1 x 1 x 1 meter, lined with magnesite bricks. They carry alternating current of about 2,000 ampères at 170 volts, and their distance from each other, which is small at the beginning of the operation, is gradually increased as the temperature rises, until the arc travels through the whole width of the furnace with a tremendous cracking and hissing noise. The electric plant is represented by two dynamos of 500 horse-power each, and one dynamo of 100 horse-power, driven by water-power.

Table No. 2 shows more exactly the working of the process in a smaller furnace, which Dr. Goldschmidt also had occasion to observe. The extraordinary purity of the iron produced by this process is due in a great measure to the purity of the Italian iron ores which were used. Suitable fluxes are added, which throw nearly all the silicon, and a considerable amount of manganese, sulphur and phosphorus, into the slag. Table No. 1 shows the composition of the charge in a case which was very closely observed, and also gives a thermo-chemical calculation of the process. Table No. 3 shows the thermic result and the calculation of the cost of production for a ton of iron under the local conditions.

TABLE NO. 1.

*Composition.*

| *Of the ore used.* | *Of the fluxes.* |
|---|---|
| $Fe_2O_3$ = 93.02 per cent. | CaO = 51.21 per cent. |

| $CO_2$ = 5.429 kg | |

THERMO-CHEMISTRY OF THE PROCESS.

*General.*

Coal, 7,500 cal
With 20 per cent. efficiency, 1,500 cal
1 hp.-hour = 653.3 cal
With 80 per cent. efficiency, 508.24 cal
Therefore, effect of 1 kg coal = effect of 3 hp. hours.
There are used:
For the decomposition of 1 gram mol $Fe_2O_3$, 192.000 cal
For the conversion of 1 kg water of 100° into steam of 100°, 637.000 cal
For the heating of 1 kg steam of 100° by 1°, 0.480 cal
For the calcination of 1 kg of flux, 425.000 cal
For the heating of 1 kg mol $CO_2$ for 1°, 0.016 cal
For the heating of 1 gr mol $Co_2$ for 1°, 0.0068 cal
For the melting of 1 kg of iron, 350.000 cal
For the melting of 1 kg of slag, 600.000 cal
By the combustion of 1 kg C to CO there are generated 2,175.000 cal

*Special.*

There are used:
For the decomposition of the oxide of iron, 93.02 × 192 ÷ 0.16 = 111,552.000 cal
For the evaporation of water from ore and coal, (1.72 + 1.21) × 637 = 1,866.41 cal
For the heating of the water vapor to 500°, 2.93 × 0.048 × 400 = 562.56 cal
For the calcination of the fluxes, 12.5 × 425 = 5,312.5 cal
For the heating of the $CO_2$ to 500°, 5.429 × 0.016 × 500 ÷ 0.044 = 987.09 cal
For the heating of the generated CO, 20.9 × 0.0068 × 500 ÷ 0.012 = 5,021.667 cal
For the melting of the iron produced, 65 × 350, 22,775.2 cal
For the melting of the slag, 13.89 × 600, 8,334.0 cal
Total, 157,311.427 cal
By the combustion of C to CO are generated, 20.9 × 2175, 45,457.5 cal
Difference, 111,853.927 cal

111,853.927 cal at 80 per cent. efficiency = 219.08 hp hours, or, as 65,114 kgs of iron are produced, per kilo of iron = 3.364 hp hours. One ton of iron, therefore, would cost in electric power at 0.0057 lire per hp hour = 19.17 lire or 15.34 marks, or about $3.83. Cost of one developed electric horse-power, 300 lire.

Yearly costs: 10 per cent. interest and depreciation, 30 lire; maintenance, 10 lire; total 40 lire, 32 marks, or about $8.

One hp hour costs, therefore $\frac{1.00}{1.000}$ = 0.0057 lire = 0.45 pfennig, or about 0.11 cent

TABLE NO. 2.

Example of an operation (in the small furnace, with 1,000 ampères and 80 volts):

Charge, 70.25 kgs, ore mixture of the following composition:

| | |
|---|---|
| Iron ore | 1,000 |
| Limestone | 125 |
| Carbon | 160 |
| Additions | 120 |

Product obtained, 308 kgs wrought iron.

The charge contained in this operation:

| | |
|---|---|
| 46.51 kg $Fe_2O_3$ | from ore. |
| 0.309 kg MnO | |
| 1.895 kg $SiO_2$ | |
| 0.25 kg CaO + MgO | |
| 0.86 kg $H_2O$ | |
| 3.263 kg CaO | from fluxes. |
| 0.194 kg MgO | |
| 0.056 kg $SiO_2$ | |
| 0.031 kg $Al_2O_3$ + $Fe_2O_3$ | |
| 2.714 kg $CO_2$ | |
| 7.234 kg C | from coal. |
| 0.310 kg Ash | |
| 0.456 kg $H_2O$ | |
| 3.552 kg C | additions. |
| 2.43 kg hydrocarbons | |
| 0.016 kg ash | |

Properties and quantity of the materials:

| Substances | Charged gr. | Obtained gr. |
|---|---|---|
| Fe | 32,557.29 | 30,727.312 |
| Mn | 239.745 | 28.336 |
| Si | 910.448 | traces |
| S | 29.000 | 15.172 |
| P | 28.000 | 2.772 |

Progress of the operation:

At 8.15 the charge commences and current is put on. At 9.15 charging is finished, and at 10.15 casting takes place. The current is regulated in such a way that, after twenty minutes, the voltage is 80 and the current 800 ampères. After a further twenty minutes 100 volts and 1,000 ampères are put on, and after thirty minutes the voltage is reduced to 70 and the current to 600 ampères. After thirty minutes more the voltage is reduced to 50 and the current to 500 ampères, and during the last twenty minutes 100 volts and 1,000 ampères are used. The total energy equals 7,200,000 volt-ampère minutes, which, at a power factor of 0.8 equals 97,200 watt hours, or 132.24 horse-power hours.

TABLE NO. 3.

Final thermic result:

| | Calories. |
|---|---|
| For the reduction of the resulting Fe are necessary $30{,}727.312 \times 192 \div 112 =$ | 52,730.262 |
| For the reduction of the Mn contained in the product are necessary $28.336 \times 94.6 \div 55 =$ | 48.719 |
| For the melting of the metal, $30.8 \times 350 =$ | 10,780.000 |
| For the melting of the slag, $6.3 \times 600 =$ | 3,780.000 |
| For the evaporation of the water and its conversion into steam of 100°, $1.316 \times 637 =$ | 838.292 |
| For the burning of the lime, $6.25 \times 475 =$ | 2,968.75 |
| For the superheating of the water vapor to 500°, $1.316 \times 400 \times 0.48 =$ | 252.672 |
| For the superheating of the $CO_2$ to 500°, $2.714 \times 500 \times 0.016 \div 0.044 =$ | 493.451 |
| For the superheating of the hydrocarbons to 500°, $2.43 \times 500 \times 0.27 =$ | 328.05 |
| For the superheating of the CO generated in the reduction of Fe and Mn $\left(3 \cdot \frac{30{,}727.312}{112} \cdot \frac{28.336}{55}\right) \cdot 500 \cdot 0.0058$ | 2860.131 |
| Total | 75,020.330 |

Heat generated by the combination of the charged C to CO during the reduction, $9.883 \times 2{,}175$ .... 21,495.525

Difference ..... 53,524.805

Therefore, as the heat furnished $= 132.24 \times 635.3 =$ 84,012.072 calories, the thermic efficiency is 61.33 per cent.

Calculation of the cost for 1,000 kg iron in a plant of 5,000 hp, producing 30 tons of steel in twenty-four hours (about 66⅔ per cent. thermic efficiency):

| | Lire. |
|---|---|
| 1,600 kg ore, at 15 lire | 24.00 |
| For pulverization of the ore, at 3 lire | 4.80 |
| 200 kg flux, at 5 lire | 1.00 |
| 250 kg cokes, at 45 lire | 11.25 |
| For pulverization of the coke, at 2 lire | 0.50 |
| 190 kg additions, at 70.0 lire | 13.30 |
| For making the mixtures, at 3.0 lire | 6.75 |
| Wear of electrodes 12 kg, at 0.30 lire | 3.60 |
| Maintenance of the furnace | 12.00 |
| Wages | 6.00 |
| Utensils | 3.00 |
| Electric power, 4,000 hp hours at 0.0057 | 22.80 |
| Incidental costs | 3.00 |
| Total | 112.00 |
| Minus volatile and combustible gases obtained, 900 cub. met. at 2 ent | 18.00 |
| Remainder, actual cost | 94.00 |

Equal to 75.2 marks, or about $18.8

| Loss on ignition, 12.630 p. c. | Loss on ignition, 15.550 p. c. |

The surprising result is gained that, by using water-power, the ton of iron can be produced for about $18.8. The item of only 3 lire for incidental costs appears, however, too small. Anyway the result of the closely watched experiment teaches that this method of producing iron and steel can come into consideration everywhere where cheap water power and pure ores etc. enter into the question. Besides Italy, Chile [illegible]

comes into consideration, and the Chilean Government has sent a representative to study the process thoroughly.

Dr. Goldschmidt came to the conclusion that, for Germany, the process could not compete with the usual metallurgical method of producing steel. For crucible steel, however, the case might be different. Eventually the process might be used in such a way that ordinary pig iron were refined in the Stassano furnace. But extended experiments are still necessary to prove such a possibility.

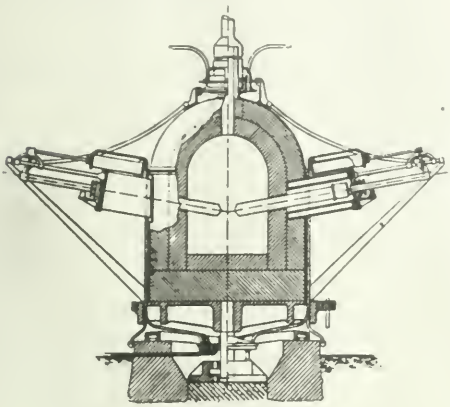

FIG. 1.—STASSANO FURNACE.

In any case, this is a method which has passed the first experimental stage, and merits serious consideration and attention. It cannot be omitted, however, to state that for the installation on a large scale a good deal of money will have to be paid yet for experience, as the Stassano works in Italy have already had about 1,000,000 lire sunk into them without having, up to this time, taken up manufacturing on a large scale. One of the drawbacks there has been that Stassano has no skilled

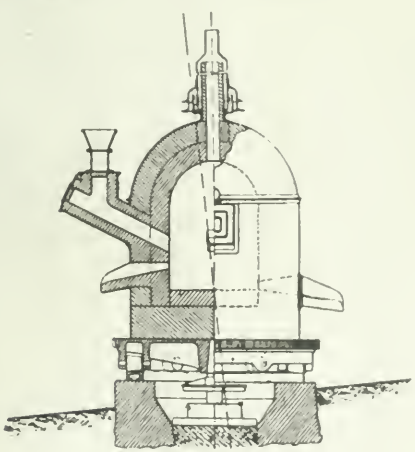

FIG. 2.—STASSANO FURNACE.

men whatever, and has to be, in fact, his own machinist, laborer, furnace man and chemist, so that he merits the greatest praise for his extraordinary zeal and tenacity in reaching the goal which he set himself.

From the above detailed figures and tables it is pretty evident that the calculations are based upon the local conditions of Italy, and that for other countries the results of the calculations would be quite different. For this reason we have given Dr. Goldschmidt's tables and calculations in full, so that our readers are enabled to recalculate the cost of the process for different conditions.

The latest form of the Stassano furnace is shown in the accompanying illustrations. Fig. 1 is a cross section of the furnace through the plane of the electrodes, and Fig. 2 is a cross section at right angles to Fig. 1. It will be noticed that the furnace is arranged for being revolved around a vertical axis. The arrangement for drawing the electrodes apart during the operation of the furnace is also plainly visible in the figures.

## SOCIETY OF ELECTROCHEMISTS AND METALLURGISTS.

The new British Society of Electrochemists was successfully inaugurated on February 4th at the general meeting held at St. Ermin's Hotel, London. After a few introductory remarks had been made by the president of the British Institution of Electrical Engineers, Mr. James Swinburne, the formal motion that the Society be formed was moved by Mr. Joseph Swan, F. R. S., and seconded by Mr. Alexander Siemens. It was stated that similar organizations for the promotion of electrochemical science and practice had been in existence for a considerable time both in Germany and the United States. The seriousness of adding to the already very great number of existing scientific societies had been keenly felt by the provisional committee, but up to the present, at any rate, owing to the peculiar nature of the sciences of electrochemistry and electrometallurgy, no satisfactory *modus vivendi* had been arrived at for affiliation with an existing organization. The following council was unanimously elected:

President, J. W. Swan; vice-presidents, Prof. A. Crum-Brown, Lord Kelvin, Sir Oliver T. Lodge, Dr. Ludwig Mond, Lord Rayleigh, Alexander Siemens and James Swinburne. Council, George Beilby, Bertram Blount, A. J. Charleton, W. R. Cooper, Sherard Cowper-Cowles, Dr. F. G. Donnan, Prof. A. K. Huntingdon, Dr. R. A. Lehfeldt, Dr. W. S. Squiere, Dr. O. J. Steinhart. The honorable secretary is F. S. Spiers, 82 Victoria street, S. W., London.

CARNEGIE INSTITUTION GRANTS.—The Carnegie Institution, through President Gilman, formerly president of Johns Hopkins University, has made five grants of money to Johns Hopkins men to assist original researches. Two of these were announced by President Remsen lately, as follows: To, Dr. Harmon N. Morse, professor of analytical chemistry, $1,500 for an assistant in his researches upon the new method he has evolved for measurement of osmotic pressures. Dr. J. B. Whitehead, in the physical department, has received a liberal grant to carry forward a research in the theory of the magnetic field developed by Maxwell..

PRODUCTION OF ZINC BY ELECTRICITY.—United States Consul Bergh sends from Gothenburg the translation of an article recently published by a local newspaper on experiments made by Dr. De Laval on the production of zinc from the ore by electricity at the factory Önan, belonging to Trollhattans Elektriska Aktiebolag, Trollhättan. It is reported that the manufacture of carbide at Önan has been discontinued and the production of zinc by Dr. De Laval's method adopted. An expert states: "Dr. De Laval has for several years worked on the problem of producing zinc by electricity from lead-sulphur-zinc ores. He was probably led to this by his experiments in trying to separate iron from ores by electricity. An examining board has reported favorably on the method, and the result has been the organization of a company to exploit the invention and the ore deposits at Saxberget, near Ludvika. The minimum capital—$256,800—has already been paid, and the company will start operations as soon as circumstances will allow."

# ANALYSIS OF CURRENT ELECTROCHEMICAL PATENTS.

By George P. Scholl.

## Electric Furnaces and Furnace Products.

*Method of Reducing Metallic Oxides.* Edward G. Acheson, Niagara Falls, N. Y. Patent No. 718,891, January 20, 1903. Application filed December 4, 1900.

*Electric Furnace.* Edward G. Acheson, Niagara Falls, N. Y. Patent No. 718,892, January 20, 1903. Application filed December 20, 1900.

In these patents Mr. Acheson describes a method for the production of metals in an electric furnace, heated by means of a core of carbon. On account of reactions taking place between the reduced metals and the carbon of the core, with the production of carbides, it has hitherto been impossible to obtain pure metals in that way. It has been proposed to prevent the metals from coming into contact with the carbon core by means of an intervening layer of inert materials, such as clay, corundum, etc. This has been more or less unsatisfactory, on account of

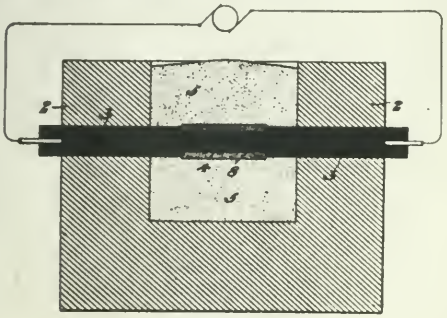

Fig. 1.—Acheson furnace.

their melting at high temperatures or undergoing reactions with the core. It is now proposed by Mr. Acheson to form this intervening protecting layer out of a refractory carbide, preferably carborundum, which is stable at the highest temperatures employed for metallurgical reactions, and does not react any more with the carbon of the core. In the manufacture of substances such as silicon or boron, which form refractory carbides, a granular carbon core is simply surrounded with the material to be reduced, mixed with carbon in proper proportion to accomplish the reduction. On passing a current through the core, the material adjacent to it combines with it to form a carbide, *i. e.*, a carbide of silicon if sand has been used in the charge. This layer of carbide incloses the core and protects it from contact with the charge. The remainder of the charge is then heated by radiation, and the metal obtained from it in a fused state by the reducing action of the carbon mixed with the charge. When the conductor is not formed of carbon granules, or where it is not desired that the core should be wasted in the formation of the carbide, a layer of the oxide to be treated, mixed with carbon in proper proportion to form a carbide, is placed around the core, and the first heating action of the current converts this layer into carbide. When the material to be reduced is alumina or another material whose metal does not form a refractory carbide, either a mixture of carbon with the oxide of silicon, boron, etc., in such proportions as to form a carbide, is placed around the core, or the core is surrounded by a layer of a finely-powdered, previously-formed carbide, such as carborundum, etc. This latter procedure is preferred, on account of the property possessed by such carbides of cohering to a dense mass of good heat conductivity. The current may be either direct or alternating, and a direct current of 30 or more ampères per square inch of cross section of conductor, when the conductor is granular, and greater when the conductor is composed of rods or plates, may be employed. The operation is carried on in a furnace, shown in Fig. 1, where 2 represents the walls of the furnace, 3, 3 the terminals of the dynamo circuit, 4 the carbon core, 8 the protecting layer of carbide and 5 the body of the charge mixture. The reduced metal will collect at the bottom, and may be tapped out or removed as a pig at the end of the operation.

*Electric Furnace.* H. N. Potter, New Rochelle, N. Y. Patent No. 719,507. February 3, 1903. Application filed November 21, 1901. Divided and filed again November 20, 1902.

The specification describes a modification of a former patent by the same inventor, abstracted in Electrochemical Industry, January, 1903, page 187. It has the same object, namely, to provide means for preventing the current to flow unevenly in electric tube furnaces, by reason of almost unavoidable slight differences in the specific resistance of the tube, due to structural, and perhaps chemical, irregularities in the tube material. The tube is composed of a mixture of magnesia and alumina, and is provided with a number of pairs of terminals. Each pair of confronting terminals is connected to a ballast resistance, which tends to maintain an even distribution of the current from all the terminals.

*Apparatus for Electro-thermally Treating Materials.* Hudson Maxim, London, England. Patent No. 719,484. February 3, 1903. Application filed August 17, 1898.

The invention relates to a furnace for the manufacture of carbides. It consists of two stationary end walls, between which is situated a crucible of fire clay, mounted on wheels, which can easily be removed. Two or more pairs of electrodes enter through one of the end walls. They are made movable, and at the beginning of the operation extend through the furnace until they touch a conductor, consisting of calcium carbide in plate form, arranged on the opposite end wall of the furnace. This conductor will provide a body of highly incandescent material to start the operation of the furnace, and as the furnace charge enters into reaction between the electrodes, they are gradually withdrawn towards the other end wall of the furnace. In this way a continuing incandescent conductor is provided, and by the time the electrodes have reached the front wall, the furnace is filled with a slab of carbide. When the electrodes are drawn out entirely, the crucible is removed and the carbide allowed to cool, while another crucible, filled with fresh charge, is put into place. Means for cooling the electrodes by a series of tubes, built in the end wall of the furnace and connected with a supply of cold water, are also described.

*Electric Furnace.* John F. Hammond, New York, N. Y. Patent No. 720,024. February 10, 1903. Application filed February 1, 1902.

The invention relates to electric furnaces for dentists' use in continuous-gum work and other work requiring a high temperature for baking. The object of the invention is to utilize the heat to the best possible advantage, and to provide for the inspection of the work without exposing it to injurious drafts. Another object is to simplify the construction and facilitate repairs, and to provide for convenient handling of the work. A furnace embodying the above principles is described in detail.

*Method of Subdividing Ingots or Blocks of Carbide.* Joseph Scales, Niagara Falls, N. Y. Patent No. 719,882, February 3, 1903. Application filed May 6, 1902.

This invention consists in a method for the subdivision of blocks or ingots of such carbides which react with water, particularly for detaching large pieces of calcium carbide from ingots formed in carbide furnaces. One or more holes are drilled into the body of the ingot while it is still very hot, and at the same time water or steam is injected into the cavity, preferably through the drill. By this means the cutting surface of the drill is preserved, and the drilling operation is facilitated on account of the local disintegration of the carbide by the steam. A wedge is then driven into the drill holes and blocks of the desired size broken off.

*Process of Making Tap-hole Plugs.* Andrew Dickey, Niagara Falls, N. Y. Patent No. 718,828, January 20, 1903. Application filed December 2, 1901. Divided and re-filed October 31, 1902.

The invention covers the process of making such tap-hole plugs as are described by the inventor in his patent No. 714,159, abstracted in ELECTROCHEMICAL INDUSTRY, January, 1903, page 189. The plugs are designed for use in carbon-lined furnaces, and are made from compressed sawdust, paper pulp or similar material, with or without the addition of a glutinous or similar binder.

## APPARATUS FOR THE ELECTROLYTIC PRODUCTION OF METALS AND COMPOUNDS.

*Recovering Tin from Scrap.* R. U. Gould, Surbiton England. Patent No. 718,927, January 20, 1903. Application filed August 27, 1900.

The process consists of two stages. In the first stage the major part of the tin is removed from the tin scraps by making them the soluble anode of a galvanic cell. The electrolyte is sea water or brine, and a cathode of carbon or a mixture of carbon, with a depolarizer like pyrolusite, etc., is employed. The construction of the cell comprises a vessel, in which is placed a wicker basket, inside of which is arranged a similar basket of smaller diameter. The annular space between the wicker baskets is filled with the tin scraps, and a cylindrical carbon cathode is placed in the middle of the vessel. In some cases it is preferred to dispense with the wicker baskets and to pile the tin scraps around a number of tinned iron bars, serving as conductors and arranged in a circle around the cathode. The iron of the scraps is said to go into solution as chloride of iron, while the bulk of the tin precipitates on the cathode and part goes into solution as chlorides of tin. In order to remove the last thin layer of tin from the scraps, they are subjected to the second stage of the process, which is purely electrolytic. They are transferred to vessels similar to the above and electrolyzed by a current furnished by the cell of the first stage in an electrolyte of caustic soda. The scraps are made the anode, and a tinned iron plate serves as cathode. An elaborate example of the working of the process is given, in which vessels 6 x 6 x 6 inches served as galvanic cells, while a vessel 3 x 3¼ x 5¼ inches was used as electrolytic cell. There is nothing said about tests of installations on a practical scale.

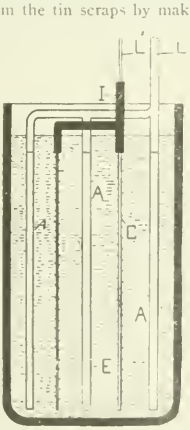

FIG. 2.—REED ELECTROLYTIC APPARATUS.

*Electrolytic Apparatus.* Charles J. Reed, Philadelphia, Pa. Patent No. 719,870, February 3, 1903. Application filed May 5, 1899.

The invention has for its object to improve the construction of amalgamated cathode plates, used in the deposition of highly electropositive metals, such as sodium, potassium, zinc, etc., in such a way as to retain the mercury on their surfaces and to prevent its tendency to work gradually downward. The means adopted consist in providing vertical plates of copper or other suitable metals with a number of horizontal grooves, serving as a receptacle for the mercury. The apparatus, shown in Fig. 2, consists of a glass or hard rubber jar J, filled with an electrolyte, *i. e.*, sulphate of zinc. The anodes A may contain the metal to be operated upon, or they may consist of platinum, lead, carbon, lead peroxide, etc. The cathode C, of copper, is provided with a series of horizontal grooves, containing mercury. The metal deposited on the plate is amalgamated, as it draws the mercury out of the grooves by capillary attraction. On re-dissolving the precipitated metals, either by connecting the cathode plate with an anode of peroxide of lead or by passing a current in the opposite direction, the liberated mercury returns to the grooves. The term "electrolytic apparatus," as used in the specification, is intended to cover also storage batteries.

*Electrolytic Apparatus.* Charles J. Reed, Philadelphia, Pa. Patent No. 719,871, February 3, 1903. Application filed May 5, 1899.

This invention is intended to facilitate the depositing action of apparatus used for the deposition of highly electropositive metals, as sodium, potassium, cadmium or zinc, and to prevent the formation of arborescent crystals. It has been found that if such metals be deposited on an amalgam of mercury and a metal nearly as electropositive as the metal to be deposited, instead of on a plate of amalgamated copper or other highly electronegative material, that the character of the deposit is entirely changed and the growth of arborescent crystals prevented. In order to obtain the best results, it is necessary that the amalgam be in the form of an incoherent mass or paste, and for this reason a mechanical support is provided, for which purpose copper has been found well suited. The cathode of the apparatus consists of a copper plate, either wholly or partly covered with the amalgam paste. The discharge of the deposited metal takes place as above.

*Electrolytic Apparatus.* Charles J. Reed, Philadelphia, Pa. Patent No. 719,872, February 3, 1903. Application filed May 5, 1900.

This specification shows several constructions of cathode plates, with the same object in view as in patent No. 719,870. Receptacles of hard rubber, shown cylindrical in form, are filled with mercury, and the lower edge of the plates projects into them through a slot in the top. The plates may also be vertically divided by means of slots, and in this case a separate mercury receptacle is provided for each section. The plates may be smooth, or they may have vertical capillary grooves.

*Electrolytic Apparatus.* Charles J. Reed, Philadelphia, Pa. Patent No. 719,873, February 3, 1903. Application filed May 5, 1899.

This invention relates to the same subject as the preceding one, and its object is to subdivide the cathode plates into a number of divisions or panels, and to provide each panel at its lower edge with a separate receptacle for mercury, so as to insure uniform amalgamation. The frame supporting the panels is protected from electrolytic action by an insulating cover, in order to prevent a loss of mercury. A large number of different constructions are shown, having rectangular, oblong and polygonal panels, with the object of facilitating the collecting of the mercury.

*Apparatus for Electroendosmotically Freeing Materials from Fluids.* Botho Schwerin, Berlin, Germany. Patent No. 720,180, February 10, 1903. Application filed April 24, 1902.

This invention relates to an improved apparatus for the process of electroendosmotically freeing mineral, vegetable and animal substances from water and other fluids, covered by the inventor in patent No. 670,350. It has been found that the thickness of the layer of material subjected to the process is of great influence, and, in the case of the treatment of peat pulp, a layer above 50 centimeters in thickness entirely prevented satisfactory results. The present apparatus, therefore, provides for the subdivision of the material into a number of small layers, to be acted upon simultaneously. To this end, the apparatus is constructed of a frame work, furnished with five corrugated metal shelves, one above the other. Wooden boxes, open at the top, having a double wire netting at the bottom and filled with the material to be treated, are put upon these shelves. The netting serves as cathode, and iron plates, resting on top of the material, serve as anodes. Means are arranged by which the anodes can be simultaneously lifted, in order to remove or insert the boxes. The water, driven out from the material by the action of the current, collects in the grooved bottoms and is drawn off. It is stated that, by connecting three apparatuses, each consisting of five shelves, each shelf receiving two anodic boxes 5 cm high, 90 cm long and 80 cm wide, in series to a 225-volt dynamo, 40 to 50 per cent. of water have been removed from peat sludge in three hours, the system requiring at the beginning a direct current of about 4 amperes, decreasing to 2½ amperes at the end.

*Electrolytic Diaphragm, and Process of Making Same.* Hugh Rodman, Philadelphia, Pa. Patent No. 720,741, February 17, 1903. Application filed March 18, 1902.

The process of making this diaphragm consists in mixing three parts of para rubber, two parts of sulphur and fifteen parts of finely-powdered potassium sulphate, and rolling the mixture out to a sheet one-sixteenth of an inch thick. This is molded and vulcanized at a temperature of 300° F. for about ten hours, taking particular care to have this heat dry. It is then soaked in running water for four or five days thus dissolving all potassium sulphate. The resulting product is suitable to be used in the decomposition of brine.

*Process of Recovering and Separating Metals from their Ores.* Hans A. Frasch, Hamilton, Canada. Patent No. 720,235, February 10, 1903. Application filed November 2, 1900.

This process is an improvement upon the inventor's former one, and is said to be particularly applicable to the treatment of copper-nickel ore and matte. The electrolytic plant proposed to carry the process into effect is illustrated in Fig 3. Any number of baths may be aranged at progressively lower levels. Each bath has in its bottom a perforated feed pipe 7 and discharge pipe 8, and an electric conductor 9, surrounded with a quantity of coarsely-disintegrated matte 10, which forms the anode. This matte is covered with a layer 11 of sand or other chemically inert granular material. Cathode plates 12 are suspended in the upper portion of the bath. Tank 14 supplies bath 2 with brine by means of pipe 13, and bath 2 overflows into tank 15, whence the brine can be raised through pipe 16 and lifting apparatus 17 into tank 18, to be returned to bath 2. By this means circulation can be accomplished. Between each two baths is arranged an automatic regulator 19, 20, 21, 22, 36. This regulator serves to adjust the overflow of the anode and cathode solution by means of their relative specific gravity. The current decomposes the brine solution in bath 2 with the production of caustic soda at the cathodes, while a chloride solution is formed in the anode compartment by the chlorine acting upon the matte. The chloride solution leaves bath 2 through pipe 29 and regulator 19, passing through pipe 32, through the anode compartment of bath 4, etc., until, from regulator 36, it flows into tank 39. The lifting apparatus 41 delivers the metallic solution, which may have been previously acidified to increase its conductivity, from tank 39 into the cathode compartment of bath 3, the baths 3, 4, 5 and 6 having been previously filled with salt brine or metallic salt solution from previous operations. The electric current is now closed between poles 42 and 43, so that the whole series of baths is in one circuit. The least positive of the metals in the chloride solution from tank 39 is deposited on the cathodes of bath 3. The copper is precipitated in the next and the following baths, as many as are necessary to precipitate it completely. The electrolyte then flows into tank 33, where it is treated with oxidizing agents and carbonate of lime, for the purpose of removing the iron. After the removal of the iron, the electrolyte is delivered by the lifting apparatus 35, through pipe 34, into the cathode compartment of bath 6, where the nickel is deposited. The electrolyte from bath 6 flows through the cathode compartments of as many baths as are required to remove the nickel, and finally, through regulator 36, into bath 37, whence it may be returned to tank 14 and used over again for circulation. Whenever the electrolyte contains enough cobalt or metals more electropositive than nickel, the latter may be removed in the same manner as the copper and nickel in an additional number of similar baths.

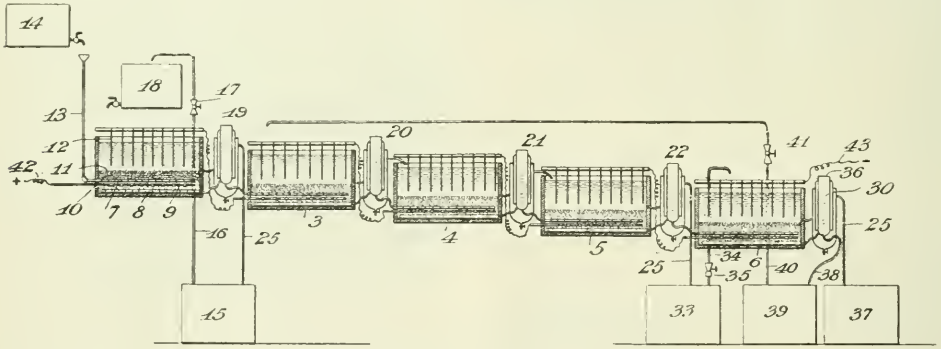

FIG. 3.—FRASCH PROCESS FOR TREATING NICKEL MATTE.

*Apparatus for Decomposing Water by Electrolysis.* W. F. Mason McCarty, Rockyridge, Md. Patent No. 721,068, February 17, 1903. Application filed April 22, 1902.

The apparatus consists of two tanks, connected by a pipe at about half their height. Each tank contains an electrode, which are so located that their upper ends are about in a line with the axis of the connecting pipe, through which the current passes from one tank to the other. Each of the two tanks has an outlet at the top, through which the gases generated may be led to suitable holders.

## STORAGE BATTERIES.

*Accumulator Plate.* Wilhelm Kraushaar, Neumuehl, Germany. Patent No. 718,774. January 20, 1903. Application filed June 20, 1902.

The inventor claims "an accumulator plate consisting of a lead plate, with thin ribs or strips on both sides thereof, which are divided by cuts, characterized by the fact that the cuts which divide the ribs into several parts are opposite to a point between the cuts in the adjoining strips, and that the parts of two neighboring ribs are united by ribs of equal height similarly arranged to the cuts, with the object of increasing the effective surface and to sufficiently stiffen the electrode and at the same time decrease the weight."

*Secondary Battery.* Isidor Kitsee, Philadelphia, Pa. Patent No. 718,037. January 20, 1903. Application filed April 28, 1900.

The object of the invention is to produce a battery of the Faure type. It is built up of individual blocks, about 4 inches long, 3/4 inch thick and 1 inch high. In order to form an electrode, the blocks can be laid upon each other with or without the interposition of a conductor. The blocks consist of a skeleton, with two face plates and three connecting lugs, consisting preferably of lead or a lead alloy. This is cast or molded, and the active material, preferably oxide of lead, is pressed into the spaces.

*Electric Accumulator Plate.* Auguste Bainville, Nanterre, France. Patent No. 719,418, February 3, 1903. Application filed July 14, 1902.

The improvement applies to storage batteries composed of rods, and consists in placing between the individual rods of a plate a corrugated sheet of insulating material. The sheet is perforated, so as to give the electrolyte access to the rods, and passes around adjacent rods of the same electrode in such a manner as to alternately cover half the circumference of each rod, covering the face of one rod and the back of the next. Thus the imperfection in the distribution of current between the plates, which may occur through the cylindrical shape of the rods, is for the greater part done away with.

*Storage-Battery Tank.* Bruce Ford, Philadelphia, Pa. Patent No. 719,778, February 3, 1903. Application filed December 11, 1902.

The objects of the invention are to provide a tank, the lining of whose compartments can be flanged all around the top of the latter, in order to prevent accumulations of acid, dust, etc., between the compartment, which would tend to produce short circuits, to provide for the draining of the acid which may find its way between the compartments and to provide a reliable, durable and efficient storage battery tank. Each compartment is lined with an acid-resisting material, such as sheet lead or antimonial lead.

*Storage Battery.* Bruce Ford, Philadelphia, Pa. Patent No. 719,937. February 3, 1903. Application filed December 10, 1902.

The specification describes means for holding down wooden separators, such as are used between the plates or elements of a storage battery, and are buoyant in the electrolyte. The holder is generally oblong and provided with curved parts, so that it can be sprung into place above the separators and, by pressing upon the walls of the jar, remains in position.

*Secondary Battery.* F. Buchanan, Dayton, Ohio. Patent No. 720,321. February 10, 1903. Application filed March 1, 1901.

The battery is constructed of an outer circular containing cell, which constitutes the negative electrode, an adjacent circular cell constituting both positive and negative electrodes and an inner electrode constituting a positive pole electrode. The intervening cell or electrode divides the electrolyte from the inner and outer electrodes. These electrodes are formed of lead, unmixed with alloys. The outer containing cell has a series of circular or spirally-arranged ribs on its inner surface; the second cell has such ribs on both surfaces, and the inner electrode on its outer surface. A number of recesses are thus formed, which are adapted to contain the active material.

*Process of Preparing Storage-Battery Plates.* R. N. Chamberlain, New York, N. Y. Patent No. 720,326. February 10, 1903. Application filed March 3, 1899.

The inventor proposes a pickling bath for storage-battery plates preparatory to forming them, which consists of a solution of 4 to 6 per cent. of nitric acid in water. The unaided action of such a solution on the lead plate would be extremely slow, but by connecting the bath in an electric circuit, so as to constitute the plate an anode, a rapid attack of the plate takes place. The lead dissolved from the plate, when it is allowed to remain in the solution, rapidly deteriorates the latter, but by the electrolytic action it is removed as fast as it is formed and deposited on a cathode, thus maintaining the efficiency of the pickling solution.

## GALVANIC CELLS.

*Galvanic Battery.* H. Halsey, New York, N. Y. Patent No. 719,059, February 3, 1903. Application filed September 21, 1901.

The specification describes in detail a galvanic cell, the carbon element of which is in the form of a disk, and movable, while the zinc element is stationary. The idea is the same as that set forth by the inventor in patents Nos. 717,394 and 717,395, ELECTROCHEMICAL INDUSTRY, February, 1903, page 218. Complicated contact devices and rubber gearings are employed. Claim 1 reads: "In a battery the combination of a case containing a plurality of independent cells, each of which contains an excitant, a horizontally-mounted revolvable shaft and an independent rotatable element, comprising a disk vertically mounted upon said shaft and immersed in said excitant, an independent driving shaft mounted upon said case and crossing the upper ends of all said cells, independent gearing between said driving shaft and each of the revolvable elements in said cells, whereby movement of the shaft causes movement of all said elements, and means for gradually feeding a chemical depolarizing agent to the excitant solution."

*Electric Battery.* H. Halsey, New York, N. Y. Patent No. 719,060. February 3, 1903. Application filed April 18, 1902.

This patent covers another construction for moving one of the electrodes of a galvanic cell or the electrolyte, or both, whereby the electrodes are brushed by the electrolyte and kept clean. An electric motor, fed by current from the battery itself, is used again to furnish the power.

*Electric Battery.* H. Halsey, New York, N. Y. Patent No. 719,061. February 3, 1903. Application filed April 18, 1902.

The main objects of the present invention are to provide a simple means for maintaining constant motion between the electrolyte and the elements of the battery, to increase the working surface of the elements, and thus increase the capacity of the battery without increasing the rise of the battery, and, further, to avoid the necessity of swiveled connections between the conductors and the elements of the battery. A steam engine is used as motive power in this case.

*Voltaic Cell.* M. E. Conrad, Atlantic, Iowa. Patent No. 719,752. February 3, 1903. Application filed December 18, 1900.

The inventor says: "In the cell of my invention polarization is prevented by the conversion of the hydrogen of polarization into sulphuretted hydrogen gas. This action is most conveniently effected by using as a negative plate a sulphide of one of the metals. The nascent hydrogen, coming into contact with the sulphide, readily unites with the sulphur to form $N_2S$, which is immediately driven off. Of the various sul

phides with which I have experimented (sulphides of iron, copper, lead and others), the sulphide of iron is superior in working entirely clean, giving a strong current and being cheap. In making my non polarizing plate of a sulphide of iron, I may use natural iron pyrites or a sulphide artificially made from a carbonate of oxide of iron." The best results are obtained by the use of zinc and sulphide of iron elements and dilute $H_2SO_4$, KOH or NaOH as the electrolyte.

*Electric Battery.* E. R. Gill, New York, N. Y. Patent No. 720,577, February 17, 1903. Application filed June 26, 1900.

The invention relates to an arrangement for making tests on electric circuits. A number of dry cells are arranged in a retaining block, and provision is made for quickly making connections between any two cells in the total series, thus obtaining the desired potential.

*Electric Battery.* M. M. Kohn, Chicago, Ill. Patent No. 720,502, February 17, 1903. Application filed July 31, 1895.

The battery belongs to the class of dry batteries having a retaining vessel made of brass, into which fits a lining of the positive electrode, zinc. The preferred electrolyte depends on the negative element employed. If it consists of copper oxide, caustic soda is used as electrolyte; in the case of carbon or peroxide of manganese, sal ammoniac is used, and in the cases of a silver compound, chloride of zinc constitutes the electrolyte. An improved construction of a carbon electrode, consisting of a series of carbon disks and depolarizer disks arranged alternately, is shown.

*Electric Battery.* V. G. Apple, Dayton, Ohio. Patent No. 720,653, February 17, 1903. Application filed June 3, 1901.

The patent describes a storage-battery cell, consisting of a containing cell made of lead or a lead alloy, cast, forced or otherwise formed together with a series of plates, running parallel to its side walls. The bars of which such plate is composed consist of a series of parallel strips, between which the active material is filled in. Another series of plates, joined to a connecting bar, is arranged between the first series of plates, forming the other electrode of the battery.

### Miscellaneous.

*Machine for Oxidizing Matrices for Electrotyping.* C. M. Oliver, Baltimore, Md. Patent No. 719,953, February 3, 1903. Application filed August 26, 1902.

The object of the machine is to apply iron filings or other fine metallic particles to the face of molds or matrices and to spread and distribute them more promptly and uniformly than heretofore. The mold which is to be electrotyped, having been prepared for oxidation, is placed in a trough which can be rocked by suitable mechanism. Iron filings or other particles are shaken down on the mold from a sieve. The trough is open, and contains a liquid, and may also contain a bag of metallic salts of a character calculated to attack the iron filings, *i. e.*, sulphate of copper. When the trough is rocked, any liquid in it is swashed back and forth over the mold, carrying with it the fine particles of metal shaken down on the mold. The waves of liquid wash the particles of metals back and forth over the mold, and the chemical in the liquid acts with great efficiency on the particles.

*Water Purifier.* Joseph Johnson, Minneapolis, Minn. Patent No. 718,935, January 20, 1903. Application filed September 23, 1902.

The apparatus is illustrated in Fig. 4 in longitudinal section, and consists of a metal pipe 2, provided at its receiving end with a nipple 3, to which the water-supply tube is attached. The pipe is divided for a portion of its length, in order to securely fasten into it, by means of lugs 8, a cylindrical insulation of glass or porcelain. This insulator fits snugly within the pipe, and is provided on its inner surface with 2 dovetailed ribs. These ribs hold the electrodes 9 and 10 in place, and, in order to provide still more electrode surface, grooves are arranged in the ribs, and flat plates 15, 16 are respectively connected by wires 17, 18 to the electrodes. The plates, as well as the electrodes, are made preferably of copper. Air tubes 18 are also provided, in order to aerate the water. As soon as the water enters that part of the pipe between the electrodes, the circuit will be closed and the stream subjected to a current of sufficiently high potential to destroy all animal or vegetable life.

*Water Purifier.* E. Kaiser, New York, N. Y. Patent No. 719,471, February 3, 1903. Application filed May 8, 1902.

The apparatus described is intended to be connected with the three-wire system. The inventor's claims read: "In an apparatus, a casing provided with a bottom portion having an

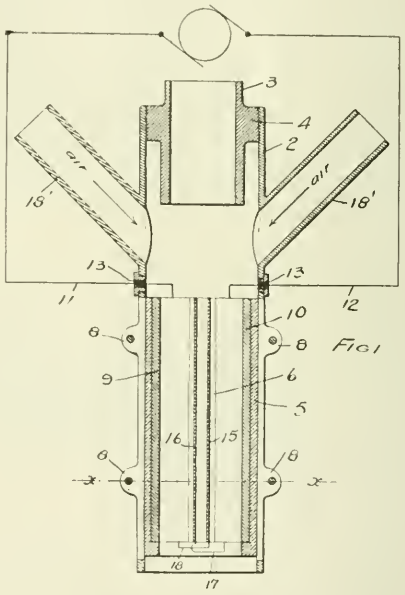

Fig. 4.—WATER-PURIFYING APPARATUS.

insulating cover, an insulating plate secured in said casing midway thereof and forming a bottom compartment, a plurality of spirally-arranged metal plates connected with said insulating plate and removable therewith, said spirally-arranged plates being divided into sets, the inner terminals of which are near the center of said compartment and the alternate plates of each set at their inner terminals, being in electrical connection with a binding post secured to the top of said insulating plate, and the outer ends of the other spiral plates being in connection with the casing, said casing being also provided at one side with a water supply, and at the opposite side with a water-discharge pipe.

---

Niagara Power in Ontario.—There is a rumor that all the important municipalities within a radius of 100 miles of Toronto will co-operate in an effort to secure a Niagara Falls power concession at the approaching session of the Ontario Legislature. It is proposed to run trunk cables from Niagara Falls east as far as Toronto and west as far as London, Ont., and supply power to the different places along the routes. It is claimed that power can thus be obtained at a cost at least 50 per cent. lower than that of the present steam-produced electrical power in Toronto, which is $40 to $60 per horse-power year.

# SYNOPSIS OF ARTICLES IN OTHER JOURNALS.

*A Summary of Articles on Electrochemistry and Allied Subjects Appearing in American and Foreign Periodicals.*

By Carl Hering.

## INDUSTRIAL ELECTROCHEMISTRY.

*Dressing Ores by Means of Static Electricity.*—The idea of using the repelling force of statically charged particles for separating finely divided ores has at last been applied in practice, and, it seems, with considerable success. The old pith-ball experiments and the dancing paper figures between two charged plates have for years been shown in schools and lectures, but although the forces are by no means very small, relatively, little or no practical use seems to have been made of them until recently. Blake and Morscher have now devised a machine based on this principle, which has been working successfully in Denver for some time. It is described, with illustrations, by Swart in the *Eng. and Min. Jour.*, January 24th. The method consists in bringing a mass of ore particles into contact with a statically-charged metallic surface. Such particles as possess relatively high conductivity are not repelled, while those of low conductivity are repelled when sufficient time has elapsed to allow them to be pulled out of their original path and caught in a separate receptacle, thus effecting a separation from the conducting material. Most of the sulphides and many of the other compounds of the valuable metals possess high conductivity, while the gangue consists largely of non-conducting material, such as quartz, mica, etc. There are exceptions on both sides; the compounds of zinc, for example, are non-conductors, thus allowing a separation to be made between pyrite, galena and chalcopyrite on the one side, and zinc blende on the other, with no preliminary roasting, dryness being the only requisite. Magnetite and pyrrhotite may also be separated from blende. A voltage of 10,000 to 20,000 is now used, the static generator being constructed almost wholly of metal, using no glass whatever, self exciting and able to run continuously in the open air without regard to atmospheric conditions and with no more attention than an ordinary dynamo receives. The separating machines, as at present constructed, have a nominal capacity of from 12 to 15 tons per twenty-four hours, working on blende concentrates at 30 mesh. As in most methods of ore dressing, the capacity is largely governed by the mesh, coarse material passing through rapidly, while the fine goes more slowly. Their machine works well on some material at 6 mesh, and will also handle material at 200 mesh with but slight change of construction or adjustment. As in other methods, sizing improves the products, but close sizing is not essential nor even desirable. On an 8 mesh jig concentrate a sizing at one near 20 mesh will usually give the best results, coarse and fine being handled separately on the same machine, which is built double for the purpose. The standard machine is a double one, 24 feet long, 41 inches wide and 81 inches high, using about 1 horse power, which generates the static charge and is the total power consumed. On the mixed sulphide concentrates of the Missouri-Kansas district, consisting of resin zinc with a greater or less admixture of pyrite and galena, the machine does its best work, as far as tests have gone. But it is not confined in its operations to ores of zinc; all metallic substances, most sulphides and arsenides, and some carbonates and oxides are thrown out of a siliceous or limy gangue, and in many instances the extraction is very high; this is particularly true of the sulphides of copper. The machine as originally constructed, makes no middlings; the finely separated products contain all the material originally charged. It can be arranged in case of coarsely crushed ores, to deliver a middlings product for recrushing when necessary. The advantages of the machine are summed up as follows: Low first cost of the machine and nominal operating expense; it separates materials without regard to their specific gravity; it works well at any mesh between 8 and 200; no roasting of sulphides is necessary; no water is required; no piece of the machine weighs 100 pounds, and any intelligent mill man or mechanic can build a machine and keep it in repair.

*Commercial Cyanide of Potassium.*—In an abstract of a paper read before the Chemical and Metallurgical Society of South Africa, published in the same ojurnal, February 28th, Whitby gives the details of some tests which he made to show how the present system of purchasing cyanide for commercial use in the gold industry left the manufacturers a very wide margin for adding impurities. It is very easy for the manufacturer to comply with existing conditions, and yet supply the consumer with a lot of things he can do without. With regard to the importance of these unnecessary impurities, alkaline carbonates takes precedence over any others as tending to increase the alkalinity of solutions; then come cyanates, which are eventually changed into carbonates, and of least importance is the presence of sulphides. In his opinion it is hard to understand why so much discredit has been attached to alkaline sulphide in the cyanide. One of his samples is a cyanide so heavily charged with sulphides as to give quite a considerable precipitate with alkaline tartrate solution, and yet has been extensively used without complaint as to its effectiveness. Laboratory experiments with fresh solutions might show that sulphides are injurious, but not in working solutions containing zinc, which precipitates them as zinc sulphide. In summarizing, he says that a mixture of sodium and potassium cyanide nicely adjusted to 98 per cent. KCy and NaCy has been used, "leaving room for extensive adulteration." The effectiveness of the mixed cyanides being accepted, it would appear desirable to adopt the use of a sodium cyanide, "dropping the fiction" of calling it potassium cyanide, and demanding an efficiency of at least 50 per cent. cyanogen. Or if potassium cyanide is to be used, some limit should be given to the sodium cyanide, merely to control the amount of inactive bodies.

*A New Method for Producing Pyrochemical Reactions.*—Although the electric furnace can be used to great advantage for many purposes, it cannot do everything as some people seem to suppose. It is not a mysterious something, but a well understood tool and like most tools it has its limitations. The science of the high tension discharge, except perhaps that less is definitely known about its action. Rasch in the *Zeit. f. Elektrochemie*, February 10th, calls attention to some of these limitations. He claims that the following requirements must be fulfilled for pyrochemical reactions in general: The electrodes must allow a high energy density and therefore a high temperature, they must not be oxidized and they must not produce a reducing action on the reaction to be obtained. In his opinion carbon will not answer, and he suggests using for pyrochemical reactions, conductors of the second class which are chemically very resistent and stand a high temperature, for instance, rods or tubes of magnesia, aluminum as do, etc., may be used in a similar way as Nernst uses them in his lamp; such resistances must be pre heated, but he does not say how. These materials may be used simply as resistances, but they may also be used as electrodes for electric discharges, but must be pre heated. He thinks the temperatures which can be

obtained in this way are the highest which can be obtained at all.

*Electrolytic Preparation of Oxygen and Hydrogen.*—An illustrated description of the Schoop system of electrolyzing water is given in the *Centralblatt f. Accum.*, February 15th. The application of the pure oxygen-hydrogen flame for soldering purposes is superior to the simple hydrogen flame, as the temperature is higher. In the Schoop system the electrodes are contained in long tubes, in order to keep the oxygen and the hydrogen separate from each other; these tubes are coated on the outside with an insulating material; the length of the tubes is chosen according to the pressure under which the gases are wanted. The following results were obtained with the Schoop apparatus during one year: One electric horse-power hour gives 97.5 liters of hydrogen and 48.75 oxygen (probably under atmospheric pressure); *i. e.*, for one cubic meter of mixed gas 6.8 horse-power hours are required; with warm acid (sulphuric acid of 1.23 spec. gravity being always used) this value is reduced to 6.2 horse-power hours; if the price of one horse-power hour is 1 cent, the cost of the production of one cubic meter of mixed gases is 4.2 to 4.8 cents. The purity of the oxygen if 99 per cent., that of the hydrogen 97.5 to 98 per cent.

*Duesseldorf Exposition.*—In the continuations of Daniell's long serial on electrochemical and metallurgical exhibits at the Duesseldorf Exposition, he gives a review of the zinc, lead, copper, silver, nickel and cobalt mines in the districts of Germany which were represented at the exposition. Exhibits of an electrotype installation of Langbein and of copper tubes of the Elmore Copper Co., are described, also of storage batteries of various German companies and the Goldschmidt thermite process. Heraeus solders aluminium, and the soldering is said to be so perfect that the soldered pieces may be worked with the hammer and may even be rolled into sheets. This process is used for making various forms of aluminium apparatus which are said to be especially suitable for use in plants in which there is danger of the occurrence of nitric acid vapors. The largest exhibit was an aluminium basin of 1,600-liter contents, soldered together from five different pieces. Exhibits of manganese and manganese alloys (manganin) and platinum are also briefly described. The electrochemical industries of Germany alone are said to consume about 1,000 kg of platinum per year. For electrical and electrochemical purposes an alloy of 90 parts of platinum and 10 parts of iridium generally is used, because this alloy has a greater mechanical resistivity than pure platinum. Platinum sheets for electrodes are made extremely thin, down to 0.03 mm. These parts will be found in the *Zeit. f. Elektrochemie*, January 15th, 29th, February 5th and 12th.

*Industrial Electrochemistry.*—J. B. C. Kershaw continues his long serial on industrial electrochemistry and electrometallurgy in the *Elec. Rev.*, giving brief notes on the progress in Europe and America. The notes refer to the Elmore electrolytic copper process, the question of the calcium carbide patents and the use of electricity for glass manufacture in *Elec. Rev.*, January 24th; nickel production in Canada; new water-power centers in America, and the electric production of iron and steel, in *Elec. Rev.*, January 31st; production and use of aluminium in the United States, electric laboratory furnaces, electric chlorates, in *Elec. Rev.*, February 7th; electrogalvanizing, the works of the Ampère Electrochemical Co., electrochemical instruction in Germany, *Elec. Rev.*, February 14th; metallic sodium as a reducing agent, nitric acid and nitrates from the air, electrolytic antimony, *Elec. Rev.*, February 21st; peat-charcoal, barium and its compounds, purification of salt and brine, *Elec. Rev.*, February 28th; the efficiency of ozonizers and carbon disulphide, *Elec. Rev.*, March 7th.

*Aluminium.*—The *Jour. de l'Elec.*, February 15th, begins an article by Pitival on the present conditions of the metallurgy of aluminium, with special references to the article of J. W. Richards in the January number of *Electrochem. Industry*. Sperry has an illustrated article on the use of aluminium in the rubber industry for making forms, in the *Metal. Ind.* (formerly *Alumin. World*), February.

*Polishing and Plating.*—Hawkins continues his illustrated serial on the polishing and plating of metals in the *Am. Jeweler*, February. He discusses sewed buffs, whole buffs, cotton-flannel wheels, rouge, tripoli, crocus, white-buffing compounds, Vienna lime, sand buffing, and scratch brushes.

*Magneto-Electric Machines for Electrometallurgical Purposes.*—There is an interesting article in the London *Elec. Rev.*, February 20th, giving some historical notes which show that magneto-electric machines, driven by engines, had been introduced into the electrometallurgical industry at a date much earlier than is often thought. From a book published in 1844 it is quoted that Woolrich, of Birmingham, "has succeeded in applying the magneto-electric current to the reduction of metals." He used two models, a smaller and a larger, "the small machine, making 1,000 revolutions per minute, deposits 120 ounces of silver per week, and the large machine, making 650 revolutions per minute, deposits from 300 to 400 ounces of silver per week. The great expense of the production of current from voltaic batteries was clearly understood at that time.

## THEORETICAL AND EXPERIMENTAL.

*A New Synthesis of Hydrocyanic Acid.*—A brief article by Gruszkiewicz describes an electrochemical method of making hydrocyanic acid which may be of practical value. The electric furnace is not suitable for such a synthesis, as its very high temperature has a decomposing effect upon the hydrocyanic acid formed. For such a synthesis a discharge method must be used in a similar way as in Bradley and Lovejoy's method for the fixation of atmospheric nitrogen. The production of hydrocyanic acid from acetylene and nitrogen by this method has been tried by Berthelot; there is the difficulty that acetylene is easily decomposed into carbon and hydrogen; Berthelot found that this complication may be avoided by adding to the mixture of gases a suitable quantity of hydrogen, about ten times as much as of acetylene; in this case he found that no carbon was deposited and that the reactions proceeded according to the equation

$$C_2 H_2 + N_2 = 2 H C N.$$

In 100 cc of a mixture of gases, containing 10 volumes of acetylene, 14.5 nitrogen and 75.5 hydrogen, Berthelot found that after the discharges had passed the mixture for one and a half hours, 8 cc (0.01 gram) of hydrocyanic acid had been formed without any deposition of carbon. The present author repeated these experiments and found that while the deposition of carbon does not take place to any such degree as in pure acetylene, nevertheless it took place, and the two ends of the electrodes were soon short-circuited by a carbon bridge; he further found that if the gas mixture did not contain more than about 5 per cent. of acetylene (and 5 per cent. nitrogen and 90 hydrogen), there was no longer any deposition of the carbon. But he believes that this synthesis is far too expensive and complicated to be of practical value. He then experimented with a gas mixture which is cheap and easily obtainable in practice, containing carbon monoxide, nitrogen and hydrogen (water gas, Dowson gas, generator gas). He found that under proper conditions hydrocyanic acid may be obtained. The reaction would take place according to the equation

$$2 C O + 3 H_2 + N_2 = 2 H C N + 2 H_2 O,$$

but the process might also follow the following equations:

$$2 C O + 6 H_2 = 2 C H_4 + 2 H_2 O$$

$$2 C H_4 + N_2 = 2 H C N + 3 H_2$$

Both assumptions would require the same composition of the gas mixture, namely 33.34 vol. C O, 50.00 vol. H, 16.66 vol. N. But with this mixture he could not get hydrocyanic acid by passing sparks through this mixture; he found, however, that it was obtained the more C O and the less H is contained in

the mixture. The best condition for the formation of hydrocyanic acid is a percentage of 49.70 to 52.44 per cent. of C O in the mixture. In his experiments he produced the electric sparks by means of a large induction coil, the primary winding of which was supplied by six storage-battery cells. To get good results the electrodes must be very close together; if they are too far apart he did not get hydrocyanic acid, whatever the composition of his mixture was. His electrodes consisted of two thin platinum wires at a distance of 3 to 4 mm from each other. As the gas mixture used by him is easily obtainable at a low cost in practice, he thinks it is not impossible that the process has a commercial future. The complete article may be consulted in the *Zeit. f. Elektrochemie*, January 22d.

*Electrolytic Superoxides.*—It has hitherto always been supposed that the lead oxide deposited at the anode of a solution of a lead salt is the binoxide or peroxide of lead, $PbO_2$, and the weight ratio of lead to this oxide has been given as 0.866, this being the ratio of the molecular weights of Pb and $PbO_2$. Hollard, however, has found that 0.866 is too great and that higher oxides are deposited; also that the proportion of these higher oxides is the greater the smaller the concentration of the lead in solution. He has investigated this subject, giving a description of his researches in *Comptes Rendus*, January 26th, an abstract of which is given in the London *Elec.*, February 20th. He used platinum electrodes, the anode being platinized, and added nitrate of copper to the bath, so as to get a compact deposit of lead. The ratio Pb to the oxide was found to vary from 0.740 to 0.861 as the concentration was increased. It is most probable that very high oxides are formed, but the author has not determined their exact nature. Lead is not the only metal which shows this phenomenon, as an alkaline solution of nickel pyrophosphate yields an oxide corresponding to the formula $NiO_4$, and a solution of sulphate of bismuth containing a little nitric acid and copper sulphate, yields an oxide of the formula $Bi_2O_5$. These have been obtained only in dilute solution, as the salts are rather insoluble.

*Electrolytic Preparation of Iodoform from Acetone.*—Abbott, in the *Jour. Phys. Chem.* for February, gives an account of a series of experiments made to find the best conditions for this process. In his experiments the cathode chamber consisted of an ordinary breaker of about 500 cc capacity; in this was placed a porous cup of about 120 cc capacity, containing the anode solution of sodium carbonate, potassium iodide, acetone and water; the cathode was a cylinder of iron-wire gauze, and the cathode liquid a 10 per cent. solution of sodium carbonate, and the apparatus was maintained at a constant temperature by means of a water bath. The most favorable conditions for the preparation of iodoform by this method were found to be the following: A current density of not more than 1.35 ampère per square decimeter, a temperature of 75 deg. C., with an anode solution consisting of six grams of sodium carbonate, 10 grams of potassium iodide, 100 cc water, and 5.5 cc acetone added at the rate of 0.5 cc every 10 minutes during electrolysis; these gradual additions are necessary, as in order to keep the acetone from oxidizing and from forming condensation products, only a small quantity must be present in the anode solution at one time.

*Action of Iodine on Alkalies.*—In the continuation of the investigation Foerster and Gyr on the action of halogens on alkalies, in the *Zeit. f. Elektrochemie*, January 1st, they treat more especially of the action of iodine. They determined the different steps in the processes and give the ionic equations representing the equilibria which characterize the different steps.

*Reduction of Potassium Chlorate.*—Bancroft (Transactions Am. Electrochem. Soc., Vol. I, page 65) and Burrows had found that they could reduce potassium chlorate to chloride Brochet, in a brief article on "a so called electrolytic reduction of potassium chlorate," agrees that in electrolyzing potassium chlorate with a copper anode, potassium chloride is obtained, the quantity of which is greater than should be theoritically expected, if a reaction according to the following equation be assumed:

$$KClO_3 + 3H_2 = KCl + 3H_2O$$

but he believes that the theory is entirely different. The ions K and $ClO_3$ act first, at the anode Cu ($ClO_3$)$_2$ is formed, and at the cathode KOH and hydrogen; these products react with one another so that K $ClO_3$ is formed again together with Cu O, which is reduced by the hydrogen to metallic copper, the latter being deposited on the bottom of the cell. He believes that this deposit is a complicated mixture of CuO, metallic copper and the chloride, for he assumes that besides the above process, which he calls the "normal" reaction, there is an "abnormal" reaction according to the equation Cu ($ClO_3$)$_2$ + 6 Cu = Cu $Cl_2$ + 6 Cu O. The reduction of the potassium chlorate is the result of an intermediate action of the metallic copper upon the chlorate. Brochet's article is contained in the *Zeit. f. Elektrochemie*, February 19th.

*Electric Analysis of Mercury.*—In the *Zeit. f. Elektrochemie*, January 1st, Glaser gives an account of an experimental study on the electric analysis of mercury and the solubility of platinum in potassium cyanide. The main results are as follows: The difference observed in the electro-analysis of mercury from a potassium cyanide solution, are due to an attack of the platinum disk serving as cathode, and to the solubility of platinum in potassium cyanide. This solubility is very small at ordinary temperatures and is greatly increased when the temperature rises. The dissolving of the platinum is accelerated considerably by potassium and sodium amalgams. The solution of platinum in potassium cyanide takes place under the development of hydrogen. In a hydrogen atmosphere, gold and silver are not dissolved by potassium cyanide, even in the presence of potassium amalgam.

*Antimony.*—A summary of the investigations on the electrolytic preparation of antimony from its ores is given by Izart in *L'Ind. Elec.*, January 10th.

*Electrons and Ions.*—Reinganum, in an article on the mechanism of electrochemistry, attempts to formulate a theory of the distribution of the electrons in the molecules entering into electrochemical reactions. He finds it necessary to assume, instead of one pair of electrons, as in Helmholtz's theory, that each molecule, say of H Cl, contains two pairs of electrons, the H atom being provided with both a positive and a negative electron, and the Cl atom likewise with one positive and one negative electron. Electrolytic "dissociation" might then be represented by the giving off of one negative electron from the H atom to the Cl atom, so that the H atom has now one positive electron, while the Cl ion has one positive electron and two negative electrons, and thus is negatively charged. When in electrolysis Cl is developed at the anode, each Cl ion gives off one negative electron and thus becomes neutral, having one positive and one negative electron. At the cathode, when hydrogen is given off, each H ion which is charged with a positive electron, receives one negative electron from the anode and thus becomes neutral, having now one positive and one negative electron. Through the external connection, the negative electrons pass from the anode to the cathode, thus completing the circuit. The author works out this idea for the different compounds and shows why the dissociation constant is a measure of chemical affinity. It is probable that the transfer of the supernumerary electron is accomplished even before actual electrolysis takes place. His article is published in the *Ann. d. Phys.*, No. 2, and is abstracted briefly in the London *Elec.*, February 13th.

*Change of Volume and E. M. F. with Pressure.*—When a Clark or a cadmium cell is put under pressure, its e. m. f. is increased, because if the current is reversed through the cell a greater amount of energy is required to maintain it constant in the case when pressure is applied, than that required when

the cell is not under pressure, it was therefore to be expected that the volume of the cell was increased, or that energy was used up in overcoming pressure. Ramsey investigated this change of volume in such cells, and its relation to the change of electromotive force due to the pressure, and published the results in the *Phys. Rev.* for February. He first gives the theory of this subject and then describes his experiments. The value, calculated by him for the increase of volume for the Clark cell, is 0.11 cb mm per coulomb, and for the cadmium cell 0.072. The values found experimentally for the Clark cell are between 0.062 and 0.232, but their mean, 0.105, is in good agreement with the calculated value. The values found experimentally for the cadmium cell are between 0.039 and 0.054, all of which are smaller than the calculated value. He thinks this was due to a bubble of air in the cell.

*Molecular Induction.* A description of some curious phenomena in electrolysis is given by Gross in the *Ber. d. Deutsch. Phys. Ges.*, No. 1, 1903, an abstract of which is pubilished in the London *Elec.*, February 6th, but unfortunately this abstract, from which the present notice was taken, is not quite clear. A square glass trough is filled with a pure concentrated solution of copper sulphate, and two copper wires, reaching nearly to the bottom, enter the vessel and are connected to a high-resistance galvanometer. "A plate of zinc is suspended in the trough across the line of current and closer to one of the wires." Copper is deposited upon the zinc and a nearly constant current is observed going from the zinc plate to the more distant electrode. On moving the zinc plate towards the latter electrode, the current is reversed. He shows that each of the suppositions that would naturally be used to explain this, namely, thermal, concentration or local currents, do not apply. A high e. m. f. may be obtained by "immersing three zinc plates, insulated on one side, into the trough," and connecting the two outside ones with the galvanometer. The author maintains that there is a force not connected with chemical affinity, and, indeed, often opposed to it, which he calls molecular induction. He presupposes some effect of molecular vibrations.

*Catalytic Action.*—Bredig and Watson give a preliminary account in the *Zeit. f. Elektrochemie*, February 5th, of an experimental investigation of the kinetic reasons underlying the fact that a solution of potassium iodide produces a catalytic action upon hydrogen peroxide, the latter being decomposed into water and oxygen.

*Electrodes Sensible to Light.*—Bose found that a cell with gold electrodes in dilute sulphuric acid, which had been charged with the 110-volt lighting current, had a different e. m. f. in the dark than when illuminated, and that the oxygen electrode was the seat of the sensibility to light. Kochan has more recently made a long series of tests with this type of cell, in which he investigated the influence of light of different colors and the action of Roentgen rays, and has published the results in the *Zeit. f. Elektrochemie*, January 8th, 15th and 22d.

*Electrolytic Galvanometer.*—In an illustrated article in the *Zeit. f. Elektrochemie*, February 5th, Heilbrun describes some experiments for demonstrating in schools or before mixed audiences that when a galvanic cell sends current through an external circuit the current flows through the electrolyte of the cell; also he says this fact is often doubted by laymen. He arranges the galvanic cell in the form of what he calls an electrolytic galvanometer by separating the anodic and cathodic liquids of the cell, placing them in two different vessels, each containing an electrode, and then connecting these two compartments by a coil, consisting of a glass tube wound in many windings and filled with the electrolyte. The magnetic action of the current flowing in this coil upon an external magnet needle can be shown, the arrangement being the same as in an ordinary galvanometer.

*Thermo Cells.*—As thermo cells are so frequently used in laboratories of electrochemists, particularly for analyses, on account of their convenience, the description in the *Zeit. f. Elektrochemie*, January 29th, of a new and more powerful one, by Heil, may be of interest here. He first gives a table of the thermo-electric forces of different materials. The greatest e. m. f. is obtained from constant an (Cu60Ni40 alloy) against an antimony-zinc alloy ($Sb_{100}Zn_{57}$); this he uses for his thermo cell. The antimony-zinc alloy becomes much more resistant to mechanical strains if about 3 per cent. of iron is added. He then describes special mechanical devices for getting the most favorable arrangement for heating. The efficiency of his thermo cell is 2.46 per cent., referring to the energy obtained in per cent. of the consumed energy, or 1.23 per cent. referring to the useful energy obtained in per cent. of the consumed energy. The corresponding figures for the more usual thermo cell (Guelcher) are 0.864 and 0.432. He claims that the efficiency of his thermo cell is superior to that of very small steam-driven dynamo sets.

## PRIMARY AND SECONDARY BATTERIES.

*The Nickel-Iron Accumulator.*—It is generally the case that as soon as someone brings out something new of promising value prior inventors crop up to show that they had done it all long before. So often is this done that it almost seems as though a patent ought to be granted to the one who makes a success of a mere idea, rather than to the prior inventor, who merely makes vague suggestions by the dozen, trusting that some will afterwards be perfected by others, in which case he claims the reward. While it would probably be impracticable to make such a change in the patent law, and as such a change might sometimes do real injustice in the other direction, yet the courts, in deciding patent-litigation cases, have the power to take cognizance of such a state of affairs and deal out justice to whom it belongs.

Whether the claims in the following article are justified or not, we give them for what they are worth, as an opinion could be expressed only after a careful investigation. The original article referred to is in the *Nya Daylight Allehanda*, a Stockholm newspaper, and an abstract is given in the *Zeit. f. Elektrochemie*, February 5th. The article claims that a battery like that of Edison's was first described by the Swedish chemist, W. Jungner. In 1899 Jungner obtained a patent, claiming a battery in which potassium hydroxide is the electrolyte, and the plates consist of powdered metallic oxides, which are insoluble in the electrolyte and give a sufficient e. m. f. Before 1900 Jungner is said to have used Cd, Cu, Fe, Mn, $AgO_2$, $Ni_2O_3$ as materials. In May, 1900, a Swedish firm bought the patents, and a few months afterwards trials were made with automobiles, which are said to have given very satisfactory results. "Without exhausting the accumulators below normal voltage, the carriage, with load, is said to have run nearly 150 kw. The weight of the carriage was 528 kg; that of the battery was 290 kg. At the end of the run the carriage had still a speed of 26.5 km per hour." The nickel-silver peroxide accumulators are, however, too expensive. It is also necessary to separate the plates by asbestos, which had become useless after 120 charges, and had to be exchanged. For this reason Jungner later used nickel oxide as a positive plate and iron as a negative plate, for which combination he obtained a patent on January 21, 1901, while Edison's patent is dated February 5, 1901. The note closes with the remark that "a jury has to decide the priority."

*Plates Made of Slabs of Active Material.*—The conclusion of Leimer's article, the first part of which was abstracted in this synopsis last month, is given in the *Centralblatt f. Accum.*, January 15th. The current for the formation of plates of 140 x 100 x 6 mm is 1.5 amperes for the positive plate; for thinner plates, a smaller current is to be used. Thick plates are best formed with nearly constant voltage, which may be 3 to 3.2 volts at the start and about 2.8 volts at the end, so that the current decreases from 3 amperes to about

¼ ampère. The result is that the core of the mass will have a crystalline, and therefore more solid, structure. The acid for forming (see the abstract last month) should be kept at 10° B. The formation should not be interrupted during the night. The ampere hours required for formation are about 35 to 45 per cent. higher than the capacity of the positive plate. For the manufacture of the negative plates, the following additional notes are given: The best composition is about three parts of minium and one part of litharge. The positive and negative plates should be formed at the same time; the latter require about twice the time of the former. The distance between the plates should be kept constant with very great accuracy, and should be equal to the thickness of the plates. After the formation, the negative plates should be kept in pure water (not in air nor in sulphuric acid). The author mentions that the positive active mass may, under certain circumstances, be a source of danger, as a few drops of glycerine on a freshly-formed positive plate cause a strong explosion after a few minutes.

### GENERAL AND MISCELLANEOUS.

*Optical Pyrometer.*—In the proper running of electric furnaces, the measurement and regulation of the temperature may sometimes be of importance, and, as probably none of the more usual instruments for this purpose are completely satisfactory, the following one, which, from the description, seems quite simple and practicable, may be of interest. It was devised by Holborn and Kurlbaum, and, as the former's name is associated with the Reichsanstalt, the apparatus is probably all that is claimed for it. It is an optical pyrometer, in which the sources to be measured are compared with a standard, which is adjusted so as to appear to merge into the source to be measured. The instrument consists of a telescope, which produces an image of the source under investigation in the plane of vision; and in the same plane is mounted the loop of an incandescent filament, contained in a circular globe, which does not perceptibly influence the optical system. A red glass, tinted with cupric oxide, is inserted in the eye piece, so that a homogeneous radiation is secured. Under ordinary circumstances a simple red surface is seen through the eye pieces, and on it the black filaments. The current is then turned on, and is increased until the filament can no longer be distinguished. The filament appears to dissolve in a fiery gas, and it is impossible to locate it except by the terminals, which remain cooler, and therefore less brilliant. The photometer or pyrometer is calibrated by means of a radiating black body, as described by Lummer and Pringheim. *Ann. d. Phys.*, No. 2; abstracted in Lond *Elec.*, February 20th.

*Acetylene Lighting for Small Cities.*—An illustrated description of the acetylene central stations in Kinkau, Griesskirchen, Poechlarn and Strass, in Austria, is given in the *Zeit. f. Calciumcarbid Feb.*, February 13th and 20th.

*Electrochemical Development.*—A summary of the development of scientific and industrial electrochemistry during the year 1902, containing brief references to articles published and patents issued during this year, is given by Krügger in the *Elektrochem. Zeit.*, January, February.

## CURRENT NOTES.

Congresses for the St. Louis Exposition.—The Board of Directors of the St. Louis Exposition voted, on February 10th, to organize an International Congress of Arts and Science in connection with the exposition, in accordance with the recommendations of the Administrative Board appointed in January to formulate a plan. The sum of $200,000 was set aside for the Department of Congresses. This sum will cover the expenses of the International Congress of Arts and Science and the publication of the proceedings thereof, and all other expenses connected with the promotion of other congresses and conventions. The Administrative Board of the International Congress of Arts and Science now consists of President Butler, of Columbia University; President Harper, of Chicago University; President Pritchett, of the Massachusetts Institute of Technology, Boston; President Jesse, of the University of Missouri; Mr. F. J. V. Skiff, director of the Field Columbian Museum, Chicago; Mr. Herbert Putnam, Librarian of Congress, Washington; Mr. Frederick W. Holls, New York, member of the Hague Tribunal. The appointment of Professor Simon Newcomb, of Washington, the eminent astronomer, as president of the International Congress of Arts and Science was confirmed, as was that of Professor Hugo Muensterberg, of Harvard University, and that of Professor Albion W. Small, of the University of Chicago, as vice-presidents of the congress. The president and vice-presidents were created a scientific committee to make detailed arrangements for the congress, subject to the general control of the Administrative Board and the director of congresses. The plan recommended by the Administrative Board was adopted by the directors of the Exposition, viz.:

There will be one general congress of arts and science, to begin September 19, 1904. The congress will have one definite task, namely, to bring out the unity of knowledge, and thus to bring harmony and inter relation into the scattered scientific work of the day. Leading scholars from the whole world will be invited to discuss every theoretical and practical science in its definite position; to trace the development of each science during the last century, and to state the open problems of to day. An honorarium and a sum for traveling expenses will be allowed to all who submit a paper in response to an invitation and who contribute a definite piece of work to the uniform plan. The plan also provides for the active participation of men of affairs. For example, the group on commerce, or on finance, or on labor, will attract business men. Groups on colonial policy, or arbitration, or municipal government, will attract politicians. The plan further provides for the participation of independent associations, national or international congresses of specialists and scientific or popular meetings.

The provision for the publication of the proceedings of the International Congress of Arts and Science, which is made in the appropriation above mentioned, will form a lasting contribution to the scientific literature of the country, and be a permanent memorial to the work of the St. Louis Exposition.

The action of the Board of Directors inaugurates the first attempt ever made at an international exposition to hold a series of related congresses, all of which should tend towards the development of one central idea. The congresses hitherto held in connection with expositions have been entirely independent, and forced to rely upon the convenience and pleasure of persons interested for their attendance. It is the first time also that a definite sum of money has been set aside to obtain the presence of men distinguished in the various fields of art, literature and science. The American Institute of Electrical Engineers is already taking steps to arrange, if possible, for an electrical congress that shall fit into the general scheme.

The official opening of the National Bureau of Standards, in Washington, will take place next summer, and numerous scientists and engineers from foreign countries are expected to attend the celebration. The date will be chosen so that when it is over, the participants may go directly to the St. Louis Congresses.

St. Louis Exposition.—Prof. J. V. Holmes, chief of the Mines and Metallurgy Department, has returned, after an absence of nearly two weeks. He visited New York City, Philadelphia, South Bethlehem, Pittsburg and Raleigh, the capital of his home State. He delivered an address before the Legislature of North Carolina, and feels confident, he says, that this State will be well represented at the World's Fair. A bill carrying an appropriation of $50,000 is now pending. The interest in the Exposition has increased wonderfully since his visit East last December.

### POROUS DIAPHRAGMS AND CELLS.

To the Editor of Electrochemical Industry:

Sir:—In 1895, while conducting experiments having for their object the simultaneous electrodeposition of gold and mercury as an amalgam upon copper or iron cathodes from solutions of those metals in solutions containing from 0.01 to 1.00 per cent. of potassium cyanide, I used vulcanized fiber in sheets and in tubular form as diaphragms and porous cells, respectively, for the separation of the anolytes from the catholytes with apparently practical success, so far as preventing the undue mixing of the two liquids. The sheet fibre, however, buckled too much to allow even approximate preservation of such plane surfaces as are desirable for diaphragms. The tubes preserved their shape.

To close the bottom ends of the tubes, I used at first soft vulcanized "corks" or stoppers. Afterwards I used soft vulcanized rubber caps, sprung over the ends so as to compress that part of the tubes, instead of expanding them, as the stoppers did while wet.

I used tubes of various diameters and lengths up to 2 feet, and thicknesses of walls from 1-32 to ⅛ inch. Such porous cells withstand the action of weak acids and alkalies indefinitely.

I never made measurements of the specific resistances of these separators. I communicate to you the above facts, trusting that they may be of practical value to workers in electrolysis. N. S. Keith.

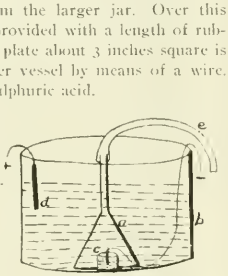
New York, N. Y., February, 1903.

### THE ELECTROCHEMICAL PRODUCTION OF HYDROGEN SULPHIDE.

To the Editor of Electrochemical Industry.

Sir:—I trust it may prove of interest to some of the readers of this paper to give a short account of my experiments in electrochemistry in the line of producing this gas, sulphide of hydrogen, by the action of an electric current upon sulphur in the presence of water. The apparatus is made up as follows: A large glass dish is provided, in the center of which is placed a much smaller vessel, say a 2-oz beaker. This smaller vessel is filled with a mixture of lead filings and powdered sulphur, and is supplied with an electrode of lead connected to an insulated wire, which leads from the larger jar. Over this beaker is placed a glass funnel provided with a length of rubber tubing, and a lead or carbon plate about 3 inches square is hung from the edge of the larger vessel by means of a wire. The vessel is filled with dilute sulphuric acid.

The following rough sketch shows the apparatus:



*a*, the glass funnel; *b*, the large glass jar; *c*, the breaker filled with lead and sulphur; *d*, the lead or carbon plate; *e*, the rubber pipe leading from funnel.

In order to generate the hydrogen sulphide the wire leading from the small beaker is connected to the negative pole of a battery or dynamo, and a current of 3 or 4 ampères sent through the apparatus.

As the water is decomposed the hydrogen unites with the sulphur, with the result that hydrogen sulphide is thrown off, and collects in the inverted funnel, from which it passes through the rubber tube into a receiving tank or pneumatic trough provided for the purpose. The oxygen liberated at the positive pole escapes into the air.

I find this a very convenient method for the generation of hydrogen sulphide, and trust it may prove of value to some of your readers. Frank Balch.

Salem, Mass., February 26, 1903.

### AMERICAN ELECTROCHEMICAL SOCIETY ELECTION.

To the Editor of Electrochemical Industry.

*Sir:*—It was not known until very recently that Mr. Alfred H. Cowles, Cleveland, Ohio, would consent to permitting his name to be used as a candidate for the presidency of the American Electrochemical Society, and therefore it is quite probable that among the list of those indorsed for the offices of the Society, that will be sent out by the Board of Management, his name will not appear.

As Mr. Cowles, with his brother, now deceased, was a pioneer in all commercial electric-furnace work; as the present great development in the commercial manufacture of aluminium had its beginning from the work of the Cowles Electric Smelting and Aluminium Co., at Lockport, and in Europe was an outgrowth of the agencies there set in operation by the Cowles brothers, and as he has probably done more than any other living individual to lay the foundation for the present great growth in the electric-smelting industries, we, the undersigned, think it would be doing both him and the Society a great honor to elect him to the presidency, and therefore we urge you to lend your support to this end.

We call your attention to paragraph 6 of the Constitution, to the effect that voting need not be restricted to the names of those on the lists sent out or indorsed by the Board of Directors.

Wm. O. Mathews, Marcus Ruthenburg, Geo. O. Knapp, Arvid Reuterdahl, Elmer A. Sperry, Wesley S. Block, Loren R. Yorce, John W. Langley, Edward R. Taylor, Isaiah L. Roberts, A. W. Smith, David H. Browne, Willard E. Case, Wm. R. Kenan, Jr., Chas. F. Mabery, Herbert H. Dow, W. L. Goodwin, F. O. Johnson, Perry L. Hobbs, Geo. O. Seward

Cleveland, Ohio, February, 1903.

To the Editor of Electrochemical Industry.

Sir:—A circular letter has recently been sent to the members of the American Electrochemical Society, advocating the election of Mr. Alfred H. Cowles to the presidency of the Society.

The undersigned, all residents of Niagara Falls, and members of the Society, venture to submit for consideration the following reasons in support of their belief that the interests of the Society would not be best subserved by carrying out the action proposed in the circular referred to:

1. The Society is but one year old. It is at present officered by the gentlemen whose brains conceived it, whose energy gave it birth and whose distinguished ability have made it, in its short life, a recognized factor in the scientific world. To us it seems that a failure to re-elect at this time the present executive officers of the Society would injure the bright prospects of the Society, and would show a regrettable lack of appreciation of the disinterested work done by those gentlemen during the past year.

2. In a representative body like this Society, there are included in its roll of members a considerable number of men whose commercial interests are unavoidably competitive, if not actually antagonistic. There are included in the roll members who are engaged in litigation with each other. While this need have no adverse influence on the good of the Society itself, it seems to us that the harmony, and hence the value and influence, of the Society would be best guarded by making it at least an unwritten rule that the principal office should be filled by a man who is not actively engaged in commercial life, and whose election could not be looked upon, even unjustly, as giving his business interests undue advantage over those of his fellow-members through the prestige which very properly would attach to such an honor being conferred by the Society.

3. It seems to us to be detrimental to the larger interests of the Society that at this early stage in its existence politics

should be injected into its affairs by a failure to observe that principle of dignity which is expressed by the sentiment that "the office should seek the man."

Lovejoy, Max Maurax, C. J. Pretzfeld, A. G. Rodgers, J. C. Roberts, T. E. Steere, E. S. Smith, F. J. Tone, C. F. Vaughn, W. M. Whitten.

Niagara Falls, N. Y., March 3, 1903.

---

To the Editor of Electrochemical Industry.

Sir:—The question of the nomination of a president of the American Electrochemical Society has been under discussion for a number of months past by some of those members whose only interest is the welfare of the Society. On the one hand the immediate re-election of a president was not considered a good precedent. On the other hand, as the Society is still so young it was thought to be very desirable at the present time to retain in office the chief officers like the president, secretary and treasurer for another year, as their experience during the first year would be of great value to the Society for the second year, after which it was thought the momentum of the machinery of its operation would be sufficient to make it safe to venture to turn it over to others.

After duly considering the pros and cons it was thought best to advocate the re-election of President Richards, and next year to add a clause to the constitution making a president and the vice presidents ineligible for immediate re-election.

It can hardly be questioned that the Society would be benefited most if President Richards would serve another year. With the exception of our indefatigable secretary, there is probably no other member who has taken such a truly unselfish interest in its welfare, and who has devoted so much of his time to its affairs. As a member of the Executive Committee I can vouch for the fact that he has done a very large amount of work, not only in his position as president, but also as the chief working member of various committees. Not only is he one of the recognized leaders of his profession in this country, but he is also a cool, calm diplomat and peacemaker of rare ability, a quality which is very important in any Society which is in danger of being rent into factions. The successful launching of this Society is due largely to what he and our secretary have done for it.

The chief question was, therefore, whether he would be willing to continue to devote so much of his time to the office. This he has consented to do. I, therefore, take pleasure in recommending his re-election. As the results of the recent votes for nominations are not secret, I am not violating a trust if I say that these nominations were overwhelmingly in favor of the re-election of the present officers. The writing of this letter is due to the fact that an effort has been made to elect someone else as president. The directors did not make any official indorsement of nominations this year for evident reasons, as they would either have been forced to nominate themselves or would have to have differed with the large majority of the members.

In the present board the electrochemists engaged in the industries are not as fully represented as would seem proper and desirable, and I would therefore recommend the election as vice-presidents of such members as E. G. Acheson, C. F. Acker, A. H. Cowles (Chas. M. Hall is already a vice-president), and Col. R. M. Thompson, notwithstanding the fact that we thereby lose on the board the valuable retiring vice presidents.

A president should, in my opinion, always be selected from the present or past officers, as he has then had an opportunity to become familiar with the management of the affairs of the Society, and has had an occasion to show whether his allegiance to it is unselfish or otherwise.

Carl Hering.

Philadelphia, March 4, 1903.

## *Book Reviews.*

Monographien über Angewandte Elektrochemie. Third volume: Die Darstellung des Chroms und seiner Verbindungen mit Hilfe des elektrischen Stromes. von Dr. Max Le Blanc, Professor of the Institute of Technology of Karlsruhe. Halle: Wilhelm Knapp. 110 pages. Price, marks 6.

The present volume is the third of the series of monographs on applied electrochemistry. It is divided into three parts, production of metallic chromium by electrolysis of watery solutions and at high temperatures, production of combinations of chromium with metals by electrolysis of water solutions and electrolysis at high temperatures, and production of combinations of chromium with non-metals. The author, who has occupied himself to a considerable extent with the electrolytic production of chromium and its compounds, has made an exhaustive study of the literature of the subject, and has collected a good deal of valuable information in this volume. The following remarks of the author, relative to the question of reproducing patent claims, will give an idea of the scope of the monograph. He says: "One can put the question on this occasion, whether it be expedient to give the contents of such phantastic specifications in a monograph. After considerable reflection, I have affirmed this question and acted accordingly. For, on the one hand, it is not always easy to draw the line between the things which ought to be incorporated and those which ought not, which is entirely an individual question; and, on the other hand, there may often be a grain of gold hidden under a mass of chaff, which might furnish a point of crystallization for later investigations or may prove to be very annoying for a later patent application. . . . The monograph, in contrast to the yearly reviews, etc., aims at a complete review of the subject under consideration, to an extent which should make unnecessary a reference to the original literature, which is sometimes not easily accessible. It wants to report everything, valuable and worthless, that has been done in the field. For these reasons I do not think a selection admissible." The reviewer is disposed to concur with the views of the author as expressed above. In times like ours, when so much is done in the different branches of science, collections like the volume under consideration are apt to be very welcome, especially to people who cannot spend all their time in following the literature. It might seem as though many of the patent claims could have been left out, but the author evidently intended to sin by commission rather than omission. On the whole, the book is a welcome addition to the literature on the subject of chromium and its compounds.

Metallurgical Laboratory Notes. By Henry M. Howe. 8vo, pp. 128. Price, $2.50. Published by the Boston Testing Laboratories, 1902.

The distinguished professor of metallurgy at Columbia University, known to the whole metallurgical world for his work in iron and steel, sets forth in these notes the guides to experimental work which he has evolved for the use of his students.

There are six groups of experiments, the first being a set of ten miscellaneous ones for those students taking a short course in metallurgy and who work in squads; the second set are ten tests in pyrometry and calorimetry, the third set are sixteen on the melting points of silicates and slags; the fourth set are nine of the properties of refractory materials, the fifth set are twenty four on iron and steel, including five tests of microstructure; the sixth set are twenty-two tests concerning other metals than iron.

The idea which has guided the selection of the experiments has been to choose such as make the student familiar with the handling of an instrument of use to the metallurgist, and at the same time illustrate, by the results obtained, some specific metallurgical principle. Professor Howe calls this the analytical system of teaching, and holds that it gives the student

the needed equipment as an investigator of the conditions of manufacture and the quality of product in such a way as can rarely be obtained in an actual industrial establishment. To this end, the experiments cover the use of pyrometers, the fusibility of slags as affected by composition, the properties of steel as affected by different heat treatment, the study of chloridizing roasting, electrolysis of copper, roasting of copper ore, desilverizing of lead by zinc, study of some cooling curves of alloys and their microscopic appearance and many other experiments, all useful and all instructive.

Not only will the student find here the most careful directions for metallurgical investigations, but anyone wishing to do experimental work of this nature for himself will find the book extremely useful. Electrochemists have frequently to conduct experiments involving the use of the same or of similar apparatus and methods, and they will find in the numerous directions and hints or suggestions much which will assist them in their experimental work. The various types of gas and electric furnaces used in the experiments, many devised by or for the author, will interest anyone doing experimental furnace work.

On the whole, we congratulate Professor Howe on the direction which his metallurgical work has taken. The university should not attempt to give the student that experience in actual practice which he can only properly obtain in the works, but it should train the man to observe, think, try and test, and so cultivate his higher faculties in a way which the industrial establishment does not do. Train the student in Professor Howe's way, and his mental alertness will, on leaving college, make up for any slight deficiency in practical experience, which latter he is in the best condition to learn quickly. The university is a place to train a man's brains, not his muscles, and the sight of a student in overalls wrestling with a refractory tap hole to miniature blast furnace in the basement of a laboratory inside the college grounds is a travesty on college education. Such is neither flesh nor fowl, *neither education nor real, practical experience;* it is largely a waste of valuable time and effort.

The teaching of metallurgy in our American universities and colleges will be greatly improved by the adoption of the methods advocated by Professor Howe, and already followed in a few of our technical schools, and we greet his book as an influential factor in that coming improvement.

Einrichtungen von Elektrolytischen Laboratorien, unter besonderer Berücksichtigung der Bedürfnisse für die Hüttenpraxis. By H. Nissenson. 8vo, pp. 51; figs., 32. Price, 3 marks. Wilhelm Knapp, Halle, 1903.

This brochure forms Volume IV of the monographs of applied electrochemistry. The author is director of the laboratory of a large metallurgical firm, and writes with a particular view to the requirements of metallurgical practice.

Ten pages are given up to a very condensed statement of fundamental electrolytic laws and general observations on batteries, conductors, measuring instruments, balances, tables and space requirements. The rest of the work describes in detail the arrangements in the laboratories for instruction at Aachen, Breslau, Clausthal, Darmstadt, Freiberg, Giessen, Konigsberg, Leoben, Munich, Philadelphia (University of Pennsylvania) and at the works-laboratories of Dumon Frères at Lüttich, the desilverization works at Hoboken, near Antwerp, and at the lead works at Stolberg, Rheinland.

The information here given is such that should certainly not be overlooked by anyone who has the problem of arranging for experimental work in electrochemistry. Numerous drawings and photographs show exactly how these successful laboratories are arranged, and the accumulated thought and experience in this line contained in this small and inexpensive book are a welcome addition to electrochemical literature.

## ELECTRICAL MACHINERY FOR OPERATING GOLD DREDGES IN THE KLONDIKE REGION.

Electrical engineers are doing pioneer work for the electrochemists and electrometallurgists. The development is that electricity is first introduced for lighting and power purposes in a metallurgical plant. When electric current is then available, the trial and introduction of electrochemical methods is only a question of time, while also depending, of course, upon the progressiveness of the managers of the plant. For this reason electrochemists should be interested in the rapidly-increasing introduction of electrical machinery in metallurgical districts.

The Western Engineering and Construction Co., San Francisco, Cal., are about to install in the territory south of the Yukon district, a power-transmission plant for the operation of a gold dredge, which will be erected at Atlin, B. C., 2 miles distant from the power plant. This is a new development in the methods of mining in this region, which is a very important placer district; and much gold that would otherwise be lost will be saved by the use of electrically-operated dredges. The work to be done here is similar to that carried on at Oroville, Cal., although the gold is coarser in the Atlin district, being found in nuggets from the size of a pin head to that of an ostrich egg.

The electrical equipment for this plant consists of the following apparatus, recently purchased from the Westinghouse Electric and Mfg. Co.: Two 180-kilowatt belted alternators, which are to be driven by water wheels; two type F variable-speed induction motors, with controllers; two standard type C induction motors for driving the pump, one of 20 horse-power and the other of 50 horse-power, and a 15 horse-power, type C motor for operating screens.

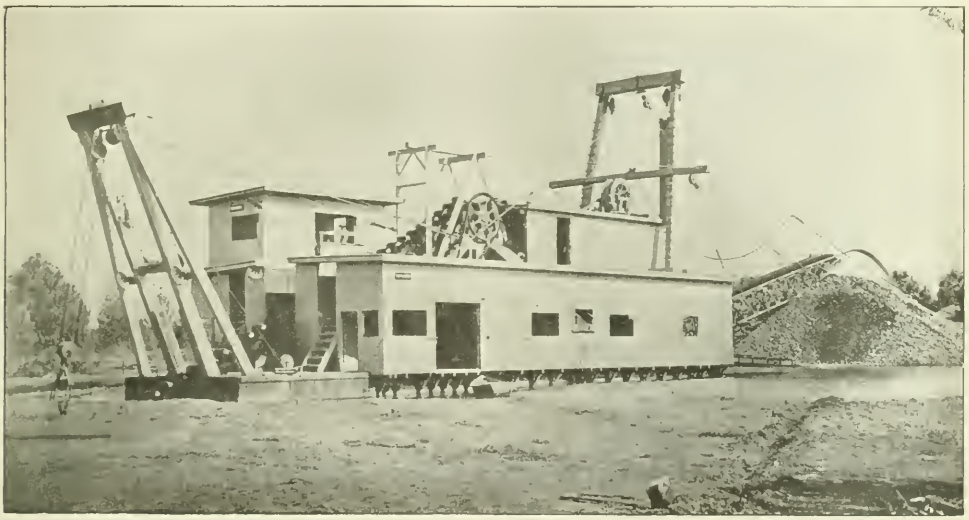
It is interesting to follow the route over which this machinery will pass before reaching its destination at Atlin. From the East Pittsburg works of the Westinghouse Co. the apparatus will be shipped directly across the continent to Vancouver, B. C., from which city it will be reshipped by steamer to Skagway. It will then be conveyed over the Chilkoot Pass to Caribou, by way of the White Horse Railway; carried by teams to Tagish Lake, where it will be reloaded on a small lake steamer and taken to a landing on the other side of the lake; then transported on a narrow-gauge road about 6 miles to another lake; reloaded on another steamer to be taken across this lake, and then freighted to Atlin.

Although all of this work has to be done in a very short season, owing to the severity of the climate, it is expected that the machinery will be in operation in July of this year, and enough gold recovered during the season to pay the entire cost of the installation, which, including the hydraulic machinery, amounts to over $150,000.

A gold dredge costs from $40,000 to $75,000, depending upon its capacity, and consists of the dredging machine proper and the pumping apparatus which supplies the necessary water for washing and sluicing. The dredge machinery comprises a chain of electrically-driven buckets, which pick up the material; a steel hopper, into which the material is emptied; a revolving screen, designed to receive and wash the excavated material; an appliance for carrying off all the coarse tailings and stones that are rejected by the screens, a sluice box, in which the water and fine material containing the gold are disposed of and in which the gold is saved. The stone chute is of a sufficient height and inclination to discharge the material clear of one side of the boat, so that no obstruction can take place on account of the accumulations of tailings. From the under side of the screen all the fine material, including the gold, is discharged with a considerable quantity of water—all of which is carried off and and over the stem of the dredge through a sluice box containing a series of riffles in which the gold is caught, and of a length sufficient to carry the tailings clear of the dredge and to save all the gold. When the gold is of too fine a character to be efficiently collected in the ordi-

nary sluice box, a finer screen and gold-saving tables are employed.

Formerly the dredging apparatus and pumps were operated by steam engines, and this practice is still largely continued. Electric power, however, is preferable, since it admits of the operation of dredges where fuel is difficult to obtain, the lighting of the dredge by electricity and, if necessary, the carrying on of the work at night. An electrically operated dredge is illustrated in the adjoining figure, showing at the left groups of incandescent lamps mounted in reflectors.



ELECTRIC GOLD DREDGE.

## ELECTROGALVANIZING.

Zinc as a protective coating for iron, after a trial of over fifty years, has proved itself to be cheaper and more effective than painting. Iron coated with zinc is called in the trade "galvanized iron" in order to characterize the nature of the protection. Whenever "galvanic" or electrochemical action is set up by the contact of iron and zinc in the presence of moisture it is the zinc which is attacked and not the iron. If the zinc coating is applied by electrolytic deposition, the process is called a cold or electrogalvanizing process to distinguish it from the hot process in which an article is coated with zinc by dropping it in a molten bath of zinc. In the following article we give a description of the electrogalvanizing process of the Cowper-Coles Galvanizing Syndicate, London.

The first care in electroplating is to have a properly prepared surface; all traces of grease and rust must be removed. Machined work, which is usually very greasy, should be immersed for about half an hour before pickling in a hot solution of caustic soda, containing about 2 pounds to the gallon of water; the work should then be placed in a hot pickle containing about 1 per cent. of commercial sulphuric acid.

The removal of mill scale from forgings and plates has always been a matter of considerable difficulty, the scale in many cases being about $\frac{1}{4}$ inch in thickness and strongly adherent. One method is to place the iron in a solution containing one part of hydrochloric or sulphuric acid to 10 parts of water for a period varying from one-half an hour to twenty-four hours. The British Admiralty specify that all steel steam pipes, boiler and collector tubes, and all plates for boilers are to be pickled in a liquid consisting of 10 parts of water and one of hydrochloric acid until the black oxide or scale formed during the manufacture is completely removed. Plates should be placed in the bath on edge and not laid flat. When taken out of this dilute acid all the surfaces are to be well brushed and washed to clean off the loose scale. They should then be placed in a bath, filled and kept supplied with fresh water, and then be placed on end to dry.

During the process of pickling large quantities of magnetic oxide and scales become detached from the plates, which, if allowed to remain in the pickle to be further acted on by the acid, form a serious source of loss. To reduce this loss to a minimum, Mr. Sherard Cowper Coles has devised a magnetic scale collector, which is shown in the adjoining figure.

The figure represents a sectional cut of a lead lined pickling tank, with a scale collector placed in position. The scale collector is connected to the electric supply mains, the current required to work it being about 10 ampères when an e. m. f. of 6 volts is employed. In the case of large baths two or more collectors may be used, or if only one is available it may be moved about to different parts of the bath at suitable intervals. From time to time the scale collector is taken out, and the adherent scale removed either by breaking the circuit or by means of a suitable brush or scraper. The apparatus is attached without any difficulty to any ordinary lead lined pickling vat, and does not require skilled labor to look after it. All the magnetic oxide or scale on the plate is collected almost as soon as it leaves the iron or steel, instead of being allowed to remain in the solution and be acted on by the acid. A large saving of acid is thereby effected.

In this country an electrical-pickling process has been tried, the solution used being sulphate of soda or sulphuric acid. The plates to be cleansed form the negative electrode, and an iron plate the positive electrode; the oxides on the surface are reduced, and any grease that may be present is decomposed. Another method is to use the plates to be cleaned as the positive pole of a galvanic cell, the negative pole being either carbon or wire gauze electroplated with silver and covered with amorphous platinum black, the electrolyte being sulphuric acid at the negative pole and a depolarizer such as nitric or chromic acid being used at the positive pole, so that the evolution of offensive odors is avoided.

Sand blasting is often used instead of pickling, and for many purposes it is found to give better results, especially for cast-

iron work from which it is very difficult to remove the last traces of acid. The process consists of projecting a stream of sand or other abrasive powder at considerable velocity against the surface to be treated. For cleaning iron work compressed air is generally used at a pressure of about 10 pounds per square inch, soft rubber tubes being used for conveying the sand and air to the nozzles, which are of cast steel. The nozzles are quickly worn away, but they are easily renewed at a small cost. The cost of sand blasting per square foot, under the most favorable conditions, including the cost of labor, sand and power, is one-twentieth of a cent, but the actual cost

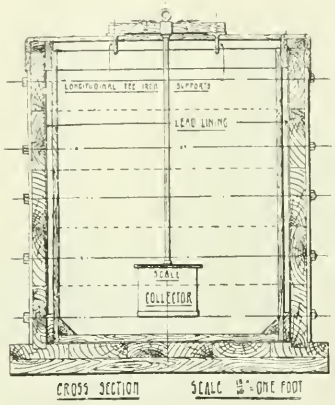


FIG. 1.—MAGNETIC SCALE COLLECTOR.

varies considerably with the nature of work. When using quartz sand of the best quality the loss is about 10 per cent. each time it is passed through the machine; the loss when using chilled-iron sand is very small, the waste of material replacing more than nine-tenths of the apparent loss.

The adjoining figures 2 and 3 show the most recent type of sand-blast equipment, as installed by the Cowper Coles Galvanizing Syndicate for cleaning castings, plates, etc. A is an air compressor; B, compressed air pipe; C, compressed-air reservoir; D, air valve; E, sand jet; F, sand-blast room; G, perforated grating; H, sand hopper; I, sand-section pipe; J, air-

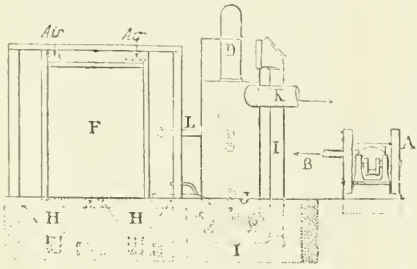

FIG. 2.—SAND-BLAST EQUIPMENT.

washing apparatus; K, inlet pipe, and L, levers for working air or sand valves.

The apparatus shown in the figures is a special one, and is combined with a dust and sand separator and sand elevator. The elevating process is effected by a current of air set in motion by an ordinary exhaust fan. The air washer J is required, if it is desired, to prevent the dust escaping with the exhaust air. This provides for the automatic return of the sand to the sand-blast apparatus in the following manner: The sand, after use, falls through the cast iron grating into the sheet-iron hoppers underneath, and is drawn by the current of air into the main pipe leading into the apparatus. The air to take the place of that exhausted enters through the roof of the room, this prevents the dust from rising. One separator only is required by this system. The size of the sand-blast plant and room is, of course, determined by the size and quantity of the work to be operated upon.

The surface to be galvanized having thus been freed from grease and otherwise cleaned, the article is ready for the zincing bath.

The process of Mr. Cowper-Coles differs from those mostly used in this country, because in the former insoluble anodes are used. He believes zinc anodes are not suitable because, whether cast, rolled, amalgamated, or in the form of granulated zinc, they fail to keep the solution up to its normal strength. As the solution therefore must be regenerated he discards zinc altogether and uses lead anodes.

The electrolyte used in the Cowper-Coles process is constituted as follows:

| | |
|---|---|
| Zinc sulphate ($ZnSO_4 7H_2O$) | 35 ounces |
| Sulphuric acid (specific gravity 1.84) | 0.1 ounce |
| Water | 1 gallon |

To obtain good, bright deposits of zinc the solution should be kept as free as possible from impurities. When the articles to be zinced are first placed in the bath it is found advantageous to use as high a current density as possible, and after a few minutes to reduce it to about 15 ampères per square foot.

For regenerating the solution the addition of zinc oxide has

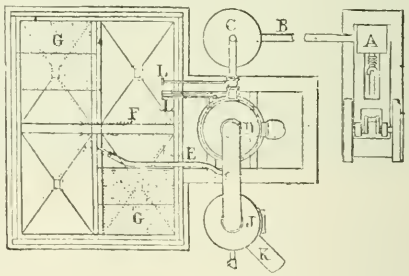

FIG. 3.—SAND-BLAST EQUIPMENT.

been suggested, but the cost is found to be too great. Mr. Cowper Coles has found the additions of zinc dust to the electrolyte to be the only practical method of accomplishing this end. The zinc dust, which contains about 75 per cent. of metallic zinc, and usually a trace of cadmium, is cheaper in the first cost than virgin spelter. The use of it also considerably reduces the waste of zinc, as practically the whole of it is consumed. Zinc dust or tultz is a grayish amorphous substance, and must not be confused with zinc oxide. It is obtained as a sublimal product in the flues of zinc-smelting furnaces. Small quantities of zinc dust are placed from time to time in the regenerating tanks, which are connected to the depositing vats by a system of piping. The electrolyte flows into the bottom of the depositing tanks by gravity, the lighter liquid being drawn off over a sill at the end or in a corner of the vat. It is advantageous to mix the zinc dust with sand or coke and thus form a filter bed, because if the zinc dust is allowed to get into the electrolyte it is found to increase the electrical resistance.

---

American Institute of Electrical Engineers.—In our last issue it was stated that the annual meeting of the American Institute of Electrical Engineers would be held in June, at Niagara Falls. We now understand that this has been found to be impracticable, as no hotel is available at that time. There is still a possibility that a joint meeting with the American Electrochemical Society may be arranged for autumn.

## ELECTRICAL EQUIPMENT OF IRON WORKS.

Electrical engineers are doing a rapidly-increasing business in installing electric-power machinery in manufacturing establishments of England, especially in the iron and steel trades. The new machinery and electric plant of Sir B. Samuelson & Co., Ltd., are now in steady and successful operation. Realizing the necessity of adopting the most approved methods of power transmission in these present times of keen competition, this company, an old and prosperous firm, have, during the past summer, installed an electric-transmission plant, including entirely new and modern apparatus, both in the driving appliances and the other machinery, in their works at Newport, in the outskirts of Middlesbrough, England. The contractors for the electrical-power installations are the British Westinghouse Electric and Mfg. Co.

The power is generated in the form of three-phase alternating currents by two steam-driven Westinghouse alternators of the rotating armature type. The steam engines run non condensing, and at a normal speed of 400 R. P. M. Steam is supplied at a pressure of 150 pounds per square inch by four Babcock-Wilcox boilers. The boilers are heated by the waste gases from a battery of coke ovens alongside, being placed between the ovens and a lofty smokestack. The flues are duplicated and fitted with dampers and by-passes, so that any number of the boilers may be heated and regulated as required. Steam-driven pumps supply water from the Middlesbrough and Stockton water-supply system. Injectors are also fitted to each boiler, and a Berryman exhaust steam feed-water heater is included in the steam equipment.

The construction of these alternators insures the best of insulation being obtained, and also renders possible the easy examination and replacing of any single-armature coil without interference with the rest of the winding. The output of each generating set is 175 kilowatts at 440 volts pressure. All of the motors and the electric lighting are supplied direct from the machines. Although rated at 175 kilowatts, the alternators have a considerable overload capacity, and are able to maintain 25 per cent. overload for long periods and 50 per cent. overload for about an hour without undue heating or chance of injury of any kind. Each machine has an exciter, driven by belt from the outer end of the main shaft, and the two exciters being exactly similar and of the Westinghouse multipolar type, four-pole, and each has a capacity of $7\frac{1}{2}$ kilowatts at 125 volts when running at a speed of 775 R. P. M. Each of these machines is capable of providing full exciting current for both alternators running at maximum rated load. The main switchboard consists of six white-marble panels, supported on wrought-iron framework, at a distance of 5 feet from the engine-room wall. There are two machine panels, one exciter panel and three feeder panels, all being fitted with the well-known type of instruments, switches, etc., that are usual in standard Westinghouse practice. The machine main circuits, and also the feeders, of each of the four sets are fitted with fuses. Each of the three feeder panels carries switches and fuse blocks for two sets, one feeder panel thus being available for extensions. The circuits are arranged for the parallel running of the main generators, which, with their exciters and switchboard, are housed in a new building erected for the purpose.

Electric power is used for the rapid handling and breaking of the coal, two motors being installed in the building set up for the accommodation of the coal breaker and elevator gear, these two machines working together and taking complete charge of the coal supply, reducing the labor item to a minimum. The capacity of this portion of the equipment is 50 tons of coal per hour. Another electric motor is installed in a shed at the base of the middle storage bin at the lower end of a conveyor belt, which carries the coal at the rate of about 25 to 30 tons per hour up an angle of 17 degrees. The fine coal is fed into the coke ovens through top doors from small wagons having collapsible bottoms, so as to permit of rapid work in charging. The coke is taken from the ovens by means of an electric ram through a vertical sliding door at each end of the ovens.

An electrically operated overhead crane of 70-foot span travels over the full length of the casting bed, and has a lifting capacity of 4 tons, the power being received from three independent motors, giving a speed of 320 feet per minute. This crane lifts the cold pigs in "comb" pieces of 2 tons or more in weight direct from the casting bed, and carries them to an ingenious breaking machine installed on a raised brick platform. The pigs, as brought forward by the crane, are laid on a long iron table, which has a loose center, to which an undulating motion is given for lifting the long "comb" of the pig forward as it comes under a set of rams. Two rams descend and grip the outer sides of the pig by pressing it down onto the solid table; a middle ram follows, striking the hollow center of the pig and breaking it into three or four pieces. The pigs are broken into lengths of about 2 feet each, and fall down a short open chute into railway cars below. The breaking process and the wagon loading is continuous and automatic. Another ram behind those mentioned serves to break the sow piece as it gradually works its way forward from the gripping ram of that side. All the motions of this machine, both those of the tables and the rams, are produced by a single electric motor, which is coupled to the breaker through spur-reduction gearing.

The nine electric motors for the purposes described are all exactly similar in construction, and in every case, it is stated, have behaved remarkably well under unusually trying conditions. They are three-phase, alternating-current induction motors, of the widely-used Westinghouse type "C" form. This motor is chiefly remarkable for the mechanical simplicity which it combines with a high electrical economy and very low maintenance and operating expenses. With the exception of the three crane motors, which require to have a certain amount of regulation, the motors are each started by means of a double-throw switch, which may be some distance from the motor if desired.

The crane motors are started and regulated by means of Westinghouse commutator type controllers. The set of these, for all three motors, is fixed in the operator's cage, which is suspended from the crane girders at the pig-breaker end, where the man in charge is in the most advantageous position for performing his work of laying pigs quickly and correctly on the breaker table. The controllers are simply designed on an extension of the principle of the starting switch mentioned, having a number of intermediate contacts for supplying various pressures to the motors.

The motor standing at the foot of the fine-coal storage bin works constantly in an atmosphere charged with coal dust, frequently being embedded in an accumulation of fine coal; and when it is cleaned out periodically a large quantity of coal is taken from it. Still it works constantly and well, never receiving any attention beyond a periodical cleaning and an occasional visit from a greaser. The two motors installed together for the operation of the coal breaker and the bucket elevators are subject to similar conditions as the one just mentioned, although to a somewhat less degree.

The motors working the coke rams are subject to high temperatures. The heat radiating from an open oven is very great, even at the distance the motor is away from the oven face. Yet these motors, as well as the crane motors, which are exposed to atmospheric elements and changes, perform the heavy duties required of them in a manner so satisfactory that it is not difficult to understand their individual reputation and the impetus they have given to the installation of electrical equipments throughout the world.

The power station is lighted by a number of incandescent lamps, arranged in pairs across the 440-volt supply mains. There are also 120 incandescent lamps and 12 arc lamps of the

inclosed type distributed to various parts of the works. The lighting system is about to be extended considerably.

The immediate effect of the electric crane and breaker for the handling of metal at the casting beds was the reduction of the staff to the extent of 23 men. The introduction of electrically-driven machinery has not necessitated the employment of new and highly trained workmen. With the exception of the power station, where the steam plant and the control of the generators and circuits call for a certain amount of skilled labor, no work of attendance beyond the ability of the untrained man of ordinary intelligence is required. The men in charge of the electric plant have been drawn from the former staff.

This saving of labor, added to the economies of floor space, transmission, running losses and low lubrication common to all electrical power installations, has made the works of Sir B. Samuelson & Co. a model that might well be copied by his competitors.

## OBITUARY.

A. T. WEIGHTMAN.

In our last issue we reported with regret the death of Mr. A. T. Weightman, formerly the chemist with the Electrical Reduction Co., of Niagara Falls. We herewith reproduce his portrait. Mr. Weightman was taken sick the last day of the Niagara Falls meeting of the American Electrochemical Society. His physician recommended him to resign his position at Niagara Falls and go to his home in England to recuperate. He went to London to undergo an operation, which resulted in his death on February 3d.

## *Personal.*

Mr. Titus Ulke, the well-known electrometallurgist, has accepted a position with the Hyland Paper Co., Johnsonburg, Pa.

Mr. Charles S. Powell, who has been associated with the Westinghouse electric interests since 1893, and who, for the past six years, has been manager of the Cleveland office of the Westinghouse Electric and Mfg. Co., has changed the scene of his activities from the United States to Europe. He has been appointed assistant manager of the British Westinghouse Electric and Mfg. Co., Ltd., and has already entered upon the duties of his new position. His headquarters are in the Westinghouse Building, Norfolk street, Strand, London, W. C.

Prof. R. H. Thurston, of Cornell University, will lecture before the New York Electrical Society next month on steam turbines.

Mr. Robert R. Moffett, Bayonne, N. J., general superintendent of the Orford Copper Co., has been visiting the principal lead and copper smelters of the West.

Mr. John Stevenson, Jr., now general superintendent of the Sharon Steel Co., Sharon, Pa., will soon resign his position, in order to undertake an extensive trip abroad.

Mr. W. B. Mucklow, Hartford, Conn., of Chapman, Mucklow & Bosson, finanical agents for the Majestic Copper Mining and Smelting Co., has been in Utah with a large party of Eastern stockholders of the company.

## TRADE CATALOGUES.

The Combination Rubber and Belting Co., Bloomfield, Essex County, N. Y., sent us their illustrated catalogue on vulcanized rubber goods adapted for mechanical purposes. Rubber tubing, to be used in connection with electric furnaces, is one of the specialties of this firm.

The Dayton Mfg. Co., Dayton, Ohio, have issued a new illustrated catalogue on the Silvey storage battery.

The Croftan Storage Battery Co., Toronto, Canada, sent us a fly leaf on their electrical automobile batteries.

The C. W. Hunt Co., West New Brighton, sent us their catalogue 0225 and pamphlet 0228 on electric hoists.

We received from the Sawyer-Man Electric Co., New York City, several fly leaves on the Sawyer-Man series railway lamp, high-voltage lamp, and reflector lamp.

The Boston Pottery Co. sent us their illustrated catalogue and price list No. 2, 1903, for all kinds of stoneware specialties, fine glazed ware, Rockingham and yellow ware and Bristol ware.

The E. T. Gleason Mfg. Co., New York City, have sent us their nicely-printed and profusely-illustrated catalogue on electric-light supplies.

## INDUSTRIAL NOTES.

The Bullock Electric Co., Cincinnati, Ohio, have secured a motor contract from the Manaduta Mining Co., Japan.

Power Plant Development.—Mr. J. H. Robeling has completed the plans for the development of a water-power electrical plant at old Limekiln Falls in the town of Stockbridge, N. Y. The plans provide for two plants, one above the other, thus using the water twice, and the combined plants will furnish 2,000 horse-power. It is proposed to use the upper power house for supply for Syracuse, and the one on the flats for the use of Oneida and Canastota. Mr. Dewitt Hadcock, of Oneida, owns the water rights.

We are informed from Concord, N. H., that the Connecticut River Power Co. have been incorporated by Brattleboro men, with an authorized capital of $200,000, which may be increased to any sum not exceeding $1,000,000. The Legislature of New Hampshire will be asked for a similar charter. The company will push the project for a dam across the Connecticut River a short distance below the railroad yard in Brattleboro. It is expected to develop here one of the greatest water-powers in New England.

Mexico.—Lauro Barra, of Mexico City, has been granted a concession by the Mexican authorities for the purpose of constructing a hydro-electric plant on the Del Valle River, in the State of Mexico, at a point called Salitrillo, about 45 miles from the city of Toluca. The franchise permits of the use of 8,000 liters of water per second.——The Dos Estrellas Mining Co. are after a concession from the Mexican authorities to permit of the utilization of 25,000 liters of water per second from the River La Ciencga. It is proposed to operate the company's reduction works by water-power and to furnish the mining town of Tlalpujahua, located in the State of Michoacan, with power for electric lighting use.——A 10,000 horse-power plant is to be constructed for the purpose of furnishing energy to operate several of the principal mines located in the El Oro district, Mexico. Jose Luis Reguena, one of the prominent mine owners in that section, has secured the requisite concession. The plant, which will be capable of developing 10,000 horse-power, will be built on the Lerma River. The current will be conveyed for a distance of about 80 miles.

Power-Transmission Plant for India.—The Federal Electric Co., 141 Broadway, New York, have taken a contract for the complete electrical equipment of a transmission plant to be constructed in India for the purpose of generating energy to be conveyed a distance of about 20 miles for both light and power

use. There will be two 150 kw, three-phase generators. The contract for the steam equipment has been awarded to a British concern on the plea of better prices and deliveries being obtained there at present.

THE A. LESCHEN & SONS ROPE CO., makers of wire rope and aerial tramways, have opened new offices at 920-922 North First street, St. Louis, Mo. They will be glad to have mining men passing through St. Louis make the office their headquarters while in the city.

THE RANSOM MFG. CO., Oshkosh, Wis., have obtained some fair-sized orders for grinding and polishing machinery for South America and Mexico.

THE GREAT NORTHERN PORTLAND CEMENT CO., Detroit, Mich., will equip their new plant throughout with electrical apparatus, and have recently purchased from the Westinghouse Electric and Mfg. Co. 23 direct-current motors, ranging in size from 5 horse-power to 50 horse-power. These motors will be applied to driving cement machinery of all kinds.

THE LLEWELLYN IRON WORKS, Los Angeles, Cal., are to be equipped throughout for driving by electric motors. Induction motors will be direct-coupled or belted to lathes, planers and other machinery, and line shafting will be entirely done away with. The Pacific Light and Power Co. have recently purchased from the Westinghouse Electric and Mfg. Co. for this plant 20 induction motors, ranging in size from 2 horse-power to 75 horse-power, which are now being installed.

THE CLEVELAND HARDWARE CO. are installing a complete electrical equipment for the operation of their plant, and have recently purchased from the Westinghouse Electric and Mfg. Co. one 75 kilowatt and one 100 kilowatt, two-phase alternators, together with exciters, switchboard, ten 20 horse-power motors and two 10 horse-power motors. The plant is already in operation, and is doing very satisfactory work. Geo. S. Rider & Co. are the engineers.

THE TERRENATES CONSOLIDATED MINING CO., Parral, Mex., have placed a contract with the Denver Engineering Works, Denver, Colo., for the installation of a complete plant for the transmission of 600 horse-power to be used for the operation of hoisting and pumping machines. Steam turbines to be built by the De Laval Steam Turbine Co., New York City, will furnish the current, which is to be conveyed by means of aluminium conductors to the hoists and pumping stations, about 1½ miles. Frank B. Rae, of New York City, consulting engineer of the Terrenates Co., will have charge of the work.

THE BISHOP & BABCOCK CO., Cleveland, Ohio, are equipping their machine shop for electric driving. The group system has been adopted and short lengths of line shafting throughout the shops are driven by Westinghouse induction motors. Seven or eight of the latter, ranging in size from 10 horse-power to 40 horse-power, have been purchased and are now in operation, current being temporarily supplied from the plant of the Cleveland Twist Drill Co., who are also equipped with Westinghouse apparatus. The Bishop & Babcock Co., however, are installing a power plant of their own, and have recently purchased a 175-kilowatt, two-phase, Westinghouse, engine-type alternator, with switchboard complete. Geo. S. Rider & Co. are the engineers for the plant.

GENERAL ELECTRIC-STANLEY.—It is stated that the much-discussed deal between the General Electric and Stanley interests has been closed, but does not include the Electric Storage Battery Co., as had been expected. The Pittsfield works of the Stanley Co. will be carried on as usual, special attention being given to high-voltage polyphan apparatus.

NATIONAL CARBON REPORT.—The annual report of the National Carbon Co. shows that the company's assets February 1, 1903, amounted to $10,324,028.88, of which $9,270,000 was in real estate, plants, machinery, etc.; $448,215.57 in merchandise, manufactured and unmanufactured, and $364,601.51 in bills and accounts receivable. The liabilities include: Preferred stock, $4,500,000; common stock, $5,500,000; accounts payable, $89,278.01, and profit and loss, $156,000.87. The net earnings of the company for the fiscal year ended January 21st were $594,371.76.

GOULD STORAGE BATTERY CONTRACTS.—Among the recent contracts closed by the Gould Storage Battery Co. are the following: Philadelphia and Lehigh Valley Traction Co.; battery to be located near Quakertown, Pa.; 196 cells in glass jars and switchboard; discharge capacity, 200 ampères. Warren Electric Street Railway Co., Warren, Pa.; 240 cells in glass jars, switchboard and Gould regulating booster; discharge capacity, 160 ampères. Dayton and Muncie Traction Co., 4 plants, located at Winchester, Ind.; Selma, Ind.; Union City, Ohio; Greenville, Ohio; each battery consisting of 305 cells in lead-lined tanks; plate capacity, 320 ampères; tank capacity, 400 ampères; switchboard and 44-kilowatt regulating Gould booster. Odell Illuminating Co.; battery located at Odell, Ill., consisting of 124 cells in jars; capacity, 240 ampere-hours at 240 volts, for three-wire lighting system. Manhattan Heat, Light and Power Co.; battery located at St. Paul, Minn., consisting of 56 cells in lead-lined tanks; capacity, 2,080 ampère hours; switchboard and automatic Gould booster for block lighting and regulation.

THE new plant of the Osceola Silica and Fire Brick Co. at Osceola Mills, Clearfield, County, Pa., will be ready early in April. The plant will have an output of 25,000,000 fire brick annually, while a large output of silica brick has also been provided for. The company were recently incorporated with $100,000 capital. Charles Rowland is president; H. W. Todd, treasurer, and R. L. Coffey, secretary and general manager.

## THE WESTON ELECTRICAL INSTRUMENT COMPANY ESTABLISH A NEW YORK OFFICE.

For the greater convenience of their numerous customers and to better care for the continued increase of business in New York and vicinity, the Weston Electrical Instrument Co., Waverly Park, Newark, N. J., have opened a New York office, at 74 Cortlandt street. This office will be under the management of Mr. Caxton Brown, who has a theoretical as well as a practical knowledge of the different instruments manufactured by the Weston Co. and their particular adaptabilities. This will enable any purchaser or any person visiting or doing business in New York, who may wish to make inquiries relative to electrical measuring instruments, to come in direct contact with a man who is properly qualified to answer such inquiries.

There will be a show room in connection with the New York office, in which will be exhibited the different types of Weston instruments and their special advantages; also the individual parts which make up the instruments. Besides being a great convenience to customers, the New York office will eliminate much correspondence in the nature of inquiries, thus reducing time of delivery of orders.

A general impression has prevailed that the Weston Electrical Instrument Co. only made voltmeters and ammeters, which is not the case. Having what are credited with being the largest and best-equipped works in the world for the production of electrical measuring instruments of all kinds, the company are particularly fitted to turn out work of any special character in which the highest excellence of mechanical and electrical work and design are the important features.

They have, in fact, been turning out a large amount of special laboratory apparatus for several years past, and are now prepared to make standard cells, standard resistances, galvanometers and the highest grade of special bridge work, speed indicators, etc.

The Weston Electrical Instrument Co. extend a cordial invitation to all interested in the subject of electrical measurements to make use of their New York office, either for the purpose of inquiry on the technical points involved or for the prospective purchasing of instruments.

## DIGEST OF U. S. PATENTS PRIOR TO JULY, 1902.

*Compiled by Byrnes & Townsend, Patent Lawyers*
*National Union Building, Washington, D. C.*

*This digest of electrochemical United States patents prior to July, 1902, will be one by classes, setting out for comparison in each class those devices which have the same object, or those methods which seek the same results. In each class the patents will be arranged chronologically. The digest will be complete in the sense of covering every point which is touched upon in the original specification.*

504,311. July 21, 1890; James Mercer, Rumford Falls, Me.

Anode compartment, a pottery cup with vertical slots through lower half, surrounded by a winding of asbestos paper. Wire gauze cathode clamped around asbestos. Cup has a side opening and reservoir for feeding salt and indicating level of electrolyte within; also a cover sealed by water or oil.

571,591. November 17, 1896; James Hargreaves, Farnworth-in-Widnes, and Thomas Bird, Cressington, England.

Electrolyses sodium nitrate, potassium iodide, etc. Cell built up of a series of frames, between which are clamped diaphragms of asbestos or glass cloth, impregnated with barium or strontium sulphate. Frames of anode compartments, pottery or glass. Frames of cathode compartments, metal, serving as terminals for cathodes. Electrolyte in second, fourth, sixth, etc., compartments only. First, fifth, ninth, etc., compartments contain exposed anodes of wire gauze or perforated plates of carbon with serrated faces, clamped against diaphragms. Third, seventh, eleventh, etc., compartments contain exposed cathodes of wire gauze or perforated metal. Introduces steam into anode compartments to volatilize and remove iodine, nitric oxide or other anion. May also run water down between anodes and diaphragm. Washes off cathode products by a water spray.

579,250. March 23, 1897; Elbridge Baker, Winchester, Mass.

Diaphragm cell, comprising a barrel or cask lined with a mixture of sand and cement. Transverse, vertical central diaphragm, also of sand and cement. Mixture contains only sufficient cement to bind the particles of sand. Feeds salt to anode compartment; brine to cathode compartment. Anode, pieces of retort carbon strung on a copper rod and joined by cement, lead being cast between the rod and the carbon pieces.

583,330. May 25, 1897; Ernest Arthur Le Sueur, Ottawa, Can.

Supplies hydrochloric acid to the anode compartment to neutralize the caustic which diffuses through the diaphragm.

589,230. July 13, 1897; L. P. Hulin, Modane, France.

One or both electrodes, a porous plate or tube, through which the electrolytic products escape, to prevent recombination. Such "filter electrode" may be of porous carbon, spongy or porous metal, a grid filled with "powders suitably agglomerated or of porous or spongy substances of the kind used in electrodes for secondary batteries," or thin, superposed metal strips or rings. Behind each "filter electrode" is a receiving compartment for the electrolytic products, which may be entirely drained or allowed to partly or entirely fill and overflow. When the level of liquid in the electrolyzing compartment is higher than in the receiving compartment, cover upper portion of active face of electrode with a rubber sheet, which extends just below the level in the receiving compartment. Electrodes may be vertical or horizontal, and may be set into and subdivide a rectangular vessel or be clamped between separate frames. Constant feed to electrolyzing compartment assists in pressing electrolytic products through electrode. May also maintain a vacuum in receiving compartment. May or may not use a diaphragm between electrodes. Examples of electrolytic products: caustic potash escaping through porous cathode and sulphuric acid escaping through porous anode.

596,157. December 28, 1897; J. Hargreaves, Widnes, England.

Cell consists of three compartments, parallel diaphragms of asbestos paper, impregnated with hydrated calcium or magnesium silicate, being clamped between an intermediate non-conducting frame and outer receiving chambers of cast iron. Anodes, a row of vertical carbon rods between the diaphragms. Cathodes, exposed sheets of copper-wire gauze clamped against outer faces of diaphragms. Sodium oxidized and washed off cathodes by steam injected into the outer compartments, which are empty. Carbon dioxide—*e. g.*, the exhaust of a gas engine or furnace—may be introduced with the steam to carbonate the product. To electrolyze ammonium sulphate, employs submerged cathodes and exposed anodes of platinum-wire gauze or serrated or perforated carbon plates, clamped against outer faces of diaphragms, the sulphuric acid being washed off. May heat cell to assist in driving off the ammonia gas.

600,081. July 5, 1898; W. S. Romme, New Rochelle, N. Y.

Electrolyses, a moistened layer of salt resting upon a perforated cathode, such as a sheet of zinc. Anodes, horizontal carbon rods in the body of salt. Constantly supplies enough water by means of perforated pipes to keep the salt moistened and wash the caustic down through the cathode. Supplies salt to the moistened layer by angular revolving grate bars above. May place a perforated tray containing lime in upper part of cell to absorb chlorine.

612,069. October 11, 1898; G. B. Baldo, Triest, Austria-Hungary.

Electrolyses sea water to produce caustic soda, hydrogen, chlorine, oxides of magnesium and calcium and sulphuric and hydrochloric acids. Employs two concentric, porous-cup diaphragms. Outer cup consists of a skeleton frame of earthenware, with superposed layers of linen, asbestos board and wire netting serving as cathode. Inner cup consists of a skeleton frame of earthenware, with superposed layers of linen, asbestos board and linen. Anodes, carbon bars in inner cup. Fills inner cup and space between cups with sea water, the space between outer cup and containing vessel being filled with fresh water. Says that magnesium and calcium oxides are precipitated between the cups. Sulphuric acid liberated at anodes, decomposing sodium chloride and producing hydrochloric acid, which is subsequently distilled off. Caustic solution drawn from containing vessel. May fill inner cup with dilute sulphuric acid, thus obtaining sulphuric acid and chlorine only as anode products.

637,410. November 21, 1899; G. H. Pond, Ashburnham, Mass.

Electrolytic cell supported transversely in the middle of an enclosure or casing, which it subdivides into two compartments. A transverse partition depends from the casing into the cell. A diaphragm of sandstone, gradually thickening toward the bottom, may extend from the partition to the bottom of the cell. Anode and cathode, plates of carbon and iron, pressed against pins projecting from walls of cell by a body of moistened salt, which is packed between them. Brine fed to salt by separate wicks leading from reservoirs to inner face of anode and cathode. Caustic solution and chlorine water run out through side openings at the bottom. Superposed perforated trays, containing lime, are placed in the casing outside the anode compartment of the cell to absorb chlorine.

637,851. November 28, 1899; H. Carmichael, Malden, Mass.

A tilting, pipe-shaped device for delivering brine from a reservoir to the cell of patent 518,710, Fig. 10.

641,820. January 23, 1900; W. Barnes, Lynn, Mass.

Maintains a vacuum over electrolyte. May electrolyze ammonium chloride and separately exhaust ammonia and chlorine. Cell may have a diaphragm, *e. g.*, a board having a rectangular opening closed by a block of superposed asbestos sheets. Float feed regulators, with insulated couplings, deliver electrolyte from reservoirs to cell. May introduce electrolyte through a hollow, cylindrical, perforated, revolving electrode.

## THE NEW YORK MEETING OF THE AMERICAN ELECTROCHEMICAL SOCIETY.

The coming general meeting of the American Electrochemical Society is the first to be held in New York City. After the meetings at Philadelphia, as the birth-place of the Society, and at Niagara Falls, as the greatest center of electrochemical industries in the world, it is, of course, New York's turn. New York City is not only the metropolis of the United States, but also the official seat of all the national engineering societies—with the only exception of the American Electrochemical Society. There can be no doubt that in due course of time this Society will also transfer its seat to New York City, and, in view of this fact, the first meeting held by the Society in New York City is of special significance. It is a question open to discussion whether a large city is the most suitable place for a convention of an engineering society. In the present case, however, the elaborate programme which we present in full on another page of this issue, leaves no doubt that the convention will be a full success and a very enjoyable affair. The programme contains a great number of papers on interesting and important subjects, and as, for the first time in the American Electrochemical Society, some of the papers will be printed in advance, we trust the discussion will bring out valuable information. The presence of Dr. Walter Nernst—famous alike as the theorist of concentration cells and as the inventor of the Nernst lamp—gives an international flavor to the meeting. There is every reason to hope that the New York meeting will turn out a success as great and enjoyable as the meetings at Philadelphia and Niagara Falls, and we hope that it will strengthen among its members the esprit de corps—the sentiment that we are all workers in the same field and enlisted in the same cause.

The New York meeting will be the *second annual* meeting—in other words, the Society now enters the second year of its life. It may be proud of the work which it has accomplished in its first year. We need to refer only to the two volumes of Transactions, which it has published, and to the membership list, which is increasing far beyond the first fondest hopes of the founders. It is significant that a large number of well-meaning scientists and engineers who, a year ago, opposed the foundation of the Society, have now become members. In the first year of its life the Society has proven to everyone that it has a mission to fulfill, and that its members are earnest in their purpose to do their duty.

The New York meeting will be the *third general* meeting of the Society. That means that the first year's work was done in only *two* large meetings. Probably the usefulness of the Society would be enhanced if more meetings would be held, at shorter intervals; of course, a meeting of one evening could be of a local character only, and this brings up the question of

the advisability of local branches of the American Electrochemical Society. New York, Niagara Falls, Philadelphia, Cleveland and Madison, Wis., have enough resident members to warrant the foundation of local branches. In various other national societies this institution of local branches has proven very successful. Of course, these local branches should always be under the control of the national Society, and the two general meetings per year should be held in future as heretofore. We think the matter is of sufficient importance to warrant a discussion by the members at the New York meeting.

## "SILOXICON."

Before the simple experiment of subjecting commingled silica and carbon to intense heat had been tried, it would have been difficult to realize that within a few years a literature equal in extent to many volumes would cluster about the reaction. The far-reaching commercial value of a seemingly simple discovery is a familiar experience, but that a reaction apparently so simple should prove so fruitful a field for research is surprising. The product first obtained was not silicon, as might, perhaps, have been expected, but its carbide. Furthermore, not one carbide, but two, appeared, the one a crystalline body of extreme hardness—carborundum—and the other amorphous and differing sharply from the first in certain of its chemical relations. Next in order it was noted that these carbides were not final, but intermediate products, and that a still higher temperature broke them down, volatilizing the silicon and leaving the carbon in the form of graphite: thus a second and most fruitful field was opened. Under proper conditions, however, it soon appeared that elemental silicon might, indeed, result from the reduction; and so the third page was turned.

From a new patent granted to Mr. E. G. Acheson and discussed in this issue's Analysis of Current Electrochemical United States Patents, it appears that a fourth product, "siloxicon," is to be added to the list—a compound, or, perhaps, a series of compounds, containing all three of the elements in the reacting bodies, possessing most unexpected properties, and resulting from a partial reduction occurring at temperatures which, comparatively speaking, are moderate. It would be hard to find a more striking illustration of the value of the intimate study of apparently simple reactions.

## TANKS.

The tank which contains the electrolyte is one of the most important pieces of apparatus in the whole range of electrochemical engineering. This may appear to be a somewhat exaggerated statement to the theorist, but every electrochemical engineer who is responsible for the satisfactory operation of an electrochemical process on a large scale, knows the difficulties and troubles involved in devising a tank which will stand the test of time. It is at once evident that there cannot be such a thing as a tank of universal applicability, suitable for any and every electrochemical process. A tank is suitable for a special electrochemical process if it is absolutely inert in the various reactions which take place during the process. Pottery ware, metal tanks, especially of iron and lead, wooden, slate, concrete tanks, etc., all of them are satisfactory for special processes, and it is the duty of the electrochemical engineer—and often not the easiest and simplest duty—to find the most satisfactory and, at the same time, cheapest material for his special purpose.

For the electrolysis of chloride solutions slate tanks have been employed to quite a large extent, and their use will certainly be continued and will even increase in future. As long as slate is free from mineral veins, there is almost no action on it by chlorine and alkalies. In an excellent article, published in this issue, Mr. David H. Browne, the chief chemist of the Canadian Copper Co., advocates the use of concrete tanks for the same purpose, and describes in detail how to construct such tanks. In view of the fact that Mr. Browne has had an extended experience of many years with the industrial treatment of chloride solutions, this article will certainly be studied with great interest by our readers. It may sound somewhat paradoxical, but it is nevertheless true, that it is easier to write down and integrate the general differential equations governing the migration of the ions in the electrolysis of chlorides, than to build a cheap tank in which the process may be carried on industrially. We must be thankful to the electrochemical engineer who describes how to do such things.

## ACETYLENE DISSOLVED IN ACETONE.

In this issue we publish a short but very interesting article by Mr. R. S. Hutton, the well-known director of the electrochemical department of Owens' College, Manchester, on a new method of storing acetylene, for which the important claim of absolute safety is made. According to Mr. Hutton, much use is already being made of this method in France, and an English company is preparing to use it extensively. We may add that the same method has also aroused considerable interest in this country for some time. The method is based upon two principles: First, the experimental fact that acetone dissolves a large amount of acetylene and that this mixture has no explosive properties; second, the use of porous material to fill up the whole space of the cylinders in which the gas is stored. This latter device is the new feature of the method, and has been suggested on account of the fact that the solution of acetylene in acetone is accompanied by a considerable increase of the volume, so that when acetylene is drawn from a cylinder in which this solution is stored, the volume of the solution would decrease and the free space thus formed would be occupied by acetylene gas, which would result in the danger of an explosion. To avoid this the use of porous material has been suggested.

This method of storing acetylene is entirely analogous to the storage of compressed oxygen and hydrogen in cylinders, which is now largely in use. The advantages of this method of storing acetylene over the direct generation from carbide are also evident and well pointed out by Mr. Hutton. On the other hand, it cannot be denied that this is a rather roundabout way of using acetylene. The cost of the cylinders and the acetone, the cost of storing and the freight charges will always be considered unnecessary expense, and the ideal at which the electrochemical engineer will continue to aim will always be the design of a simple, cheap and absolutely safe generator of acetylene directly from carbide. It is similar

with the use of compressed oxygen and hydrogen gases in cylinders. They will be used wherever small quantities are needed at a certain place, but if oxygen and hydrogen are needed in considerable quantities at one and the same place, it will be cheaper not to buy the compressed gases, but to install an electrolytic water decomposition plant. With acetylene the conditions are analogous, and for acetylene lighting installations it will always be preferable to use generators for the direct production of acetylene from calcium carbide. However, until the ideal method for this purpose has been found, the method of storing acetylene in acetone will render very valuable service, and we hope with Mr. Hutton that the influence of this method on the carbide industry will be of the most satisfactory nature in opening up many new uses for acetylene gas.

## "OXYGEN-LIFT" STORAGE BATTERIES.

In the Synopsis of last month we printed an abstract of an article in a Swedish contemporary which claims priority for a Swedish chemist, Mr. Jungner, over Mr. Edison in the invention of the celebrated nickel-iron battery. Without wishing at present to discuss this claim, we may record the fact, which does not seem to be generally known, that the general idea of an "oxygen-lift" cell—*i. e.*, of a storage battery in which the electrochemical action consists in the transfer (or "lifting") of oxygen from one plate to the other—is as old as the storage battery itself. When the lead storage battery was invented, involving lead peroxide and lead as the two electrodes in the charged condition, it was thought that during discharge they were changed into lead oxide; the use of sulphuric acid was thought to be necessary only for increasing the conductivity of the electrolyte. We now know that the function of the sulphuric acid is entirely different, and that the lead cell is not an oxygen lift cell. This is one of the many instances of a general, though vague idea of an invention existing long before the real invention was made, or before it was reduced to practice. Of course, such references to prior vague ideas should not have undue weight in deciding who should have the real credit for having accomplished something useful and practical.

## INSULATING VARNISH FOR ELECTRIC MACHINERY.

In this issue we publish a very interesting paper by Mr. C. E. Farrington on defective machine insulation. The subject is of the utmost importance for the electrical engineer who has to construct his dynamos and motors in such a strong and durable manner that they will fulfill their duty even under severe conditions. As Mr. Farrington says, the designer of a motor never can tell which one of his machines will be located in the hottest corner of a rolling mill or may have to stand some day an emergency load in ordinary practice. The design of electric machinery, based upon most exact mathematical theory, has attained in recent years such a degree of perfection that it is safe to say that the weakest points of up-to-date electrical machinery are due to defects of the materials used. The insulating varnish may appear, at first sight, a small detail, but it becomes a matter of considerable importance in view of the undeniable fact that a great many electrical machines are crippled in practice on account of the use of defective insulation.

It is not difficult to understand this condition of things. Electrical designers are always excellent mathematicians and mechanical and electrical engineers, but generally no chemists. The problem of devising a good insulating varnish, however, is a chemical problem. We note with pleasure that among the papers to be read at the New York meeting of the American Electrochemical Society there is one by Dr. M. von Recklinghausen on insulating materials, a field for chemists. On account of its enormous importance for the electric fraternity, this is indeed a field which will be found to be quite lucrative to the chemist who solves the problems involved in this matter.

Speculative minds have asked why one should look for insulating materials, insulating varnishes and paints and the like, as it would be much simpler to cover the copper wire directly with some metallic cover of perfect insulating properties. This is of course only a very vague suggestion and without any value for the practice as long as this coating is not clearly defined. Nevertheless, it is not an absolutely impossible thing, and if a copper compound could be found which has the necessary mechanical, chemical and electrical properties, and which could be easily formed in a thin continuous layer on the surface of copper wire, this would certainly represent the ideal insulation. To quote an analogous, although quite different case, we may refer to the recent brilliant invention of Mr. Acheson, who covers the electric furnace carbon with a sheath of carbide, which is, at the same time, stable at the highest temperature and a good conductor of heat, and thus makes the production of pure metals possible in the electric furnace, while it had been impossible before on account of reactions taking place between the reduced metals and the carbon of the core. But it is useless at present to speculate about possibilities of insulating copper wire with a sheath of insulating copper compound which has, at the same time, all the other required mechanical and chemical properties.

The actual situation is clearly pointed out in Mr. Farrington's article. The copper wire, used in practice, is covered with cotton and an insulating varnish or paint is used for the sole purpose of making constant the initial insulation resistance of the cotton covering. It is therefore important to study the weaknesses of the cotton covering in order to correct them. Mr. Farrington discusses the principal defects of the cotton covering in detail, and, starting from these fundamental facts, he describes in a very interesting manner the long series of tests, extending over a number of years, to find the best constitution of an insulating varnish for general electrical practice. While it is to be regretted that, for commercial reasons, Mr. Farrington does not describe exactly the constitution and manufacture of his insulating compound, the paper is none the less interesting in view of the clear explanation of the reasons why certain materials should *not* be used in an insulating varnish.

## NEW YORK MEETING OF THE AMERICAN ELECTROCHEMICAL SOCIETY.

In our last issue we printed the programme of the coming New York meeting of the American Electrochemical Society. As in the meanwhile this programme has been extended or changed in some particulars, we give here again the full programme for the convenience of our readers.

Members and guests will please register at the *Chemists' Club*, 108 West Fifty-fifth street, and receive their badges as soon after their arrival as possible. Badges will be given to all members in good standing and to applicants who have deposited their initiation fee. Special badges will be provided for guests, who must be introduced by a member. All meetings will be held in the large assembly hall of the Chemists' Club, where members in attendance may have their mail addressed, and where all announcements will be made. By the courtesy of the Chemists' Club, its club house, including the library of the American Chemical Society, will be open for the use of members and visitors.

The hotel headquarters of the Society during the meeting will be at *The Wellington*, Seventh avenue and Fifty-fifth street, half a block from the Chemists' Club.

By the courtesy of the *German Liederkranz*, its club house, 111 to 119 East Fifty-eighth street, will also be open to members and guests during the convention. Membership buttons will secure admittance.

On Thursday morning, April 16th, at 9 A. M., a meeting of the Board of Directors will be held, which will be followed, at 10 A. M., by the business meeting of the Society, at which reports of directors and officers will be presented.

Reading and discussion of the following papers: Wilder D. Bancroft, Ph.D., "Constant Voltage and Constant Current Separations;" H. T. Barnes, Ph.D., "Experimental Study of Some Electrode Effects;" J. W. Richards, Ph.D., and W. S. Landis, "The Electrolysis of Water;" Wilder D. Bancroft, Ph.D., "Experiments with Metallic Diaphragms;" C. J. Reed, "Protective Action of Zinc Chloride on Metallic Iron."

At 1 P. M. luncheon will be served at the Chemists' Club, by invitation of the New York members. At 2.30 P. M. reading and discussion of the following papers: Max von Recklinghausen, Ph.D., "Insulating Materials—A Field for Chemists;" H. B. Coho, "A Historical Review of the Storage Battery," with illustrations; Elmer A. Sperry, "The Use of Pyroxyline in Electric Storage Batteries;" W. H. Walker, Ph.D., "The Concentration Changes in the Electrolysis of Brine;" J. W. Walker, Ph.D., "The Influence of Some Impurities in Salt Upon the Yield of Soda by the Amalgam Process;" A. A. Knudson, "The Corrosion of Metals by Electrolysis;" Titus Ulke, "Modern Electrolytic Copper Refining;" N. S. Keith, Ph. D., "A Note on the Composition of Electroplating Solutions;" C. W. Volney, Ph.D., "The Formation of Nitric Acid Under Electric Influences."

At 7 P. M., reception of members and guests in the clubhouse parlors of the German Liederkranz, 111-119 East Fifty-eighth street. At 8 P. M., subscription banquet for members and guests. Ladies are especially invited to participate. The price per cover is $5. A fine musical programme has been arranged.

Friday morning, April 17th, 9.30 A. M., announcement of the results of the election of officers for 1903. Reading and discussion of the following papers: W. D. Bancroft, Ph.D., "Note on Electrical Endosmose;" Louis A. Parsons, Ph.D., "Ions and Electrons;" Carl Hering, "Uniformity in Electrochemical Equivalent;" W. D. Bancroft, Ph.D., "The Electromotive Force of Alloys;" Prof. C. F. Burgess and Carl Hambuechen, Ph.D., "Electrolytic Production of Metallic Compounds;" J. G. Zimmermann, "The Electrodeposition of Metals Upon a Rotating Cathode."

At 1 P. M. luncheon will be served at the Chemists' Club, by invitation of the New York members.

At 2 P. M., excursions to plants and places of interest, as arranged by the Excursion Committee, starting from the Chemists' Club. Three parties are scheduled for this afternoon, each one starting at 2 P. M. The first party visits the Willyoung & Gibson Co. and the works of the Crocker-Wheeler Co., at Ampere, N. J.; the second, the works of the Sawyer-Man Electric Co., the special exhibition at the store of Eimer & Amend and the Cooper Union Institute; the third, the plant of the United States Electrogalvanizing Co. in Brooklyn and the Brooklyn Navy Yard.

At 8.30 P. M. the Society will, by special invitation, be the guests of the American Institute of Electrical Engineers at their extra meeting, held in the assembly hall of the Chemists' Club, at which the programme is as follows: President Scott, "Introduction;" W. J. Hammer, "Radium and Other Radioactive Substances, and Certain Phosphorescent and Fluorescent Substances." "The Properties and Applications of Selerium." "The Treatment of Disease by Ultraviolet Rays."

On Saturday morning, April 18th, 9.30 o'clock, the following papers will be read and discussed: A. B. Marvin, "Electrolytic Conduction Without Electrodes;" P. G. Salom, "A New Type of Electrolytic Cell;" H. E. Patten and W. R. Alott, "Potentials of Zinc in Aqueous Solutions;" Woolsey McA. Johnson, "Notes on Electrolytic Depositions of Nickel;" Alfred H. Cowles, "What is the Capacity of Molecules for Electric Charge in Electrolysis?" B. McNutt, "An Electric Laboratory Furnace;" J. A. Steinmetz, "Exhibit of Aluminium Corrosion;" August Eimer, "Exhibit of New Apparatus."

At 1 P. M. luncheon will be served at the Chemists' Club, by invitation of the New York members.

At 2 P. M. excursions will be undertaken to plants and places of interest, as arranged by the Excursion Committee, starting from the Chemists' Club. Two parties are scheduled for this afternoon, the first visiting the New York Edison Station at Thirty-eighth street and East River, the Seventy-fourth street power house of the Manhattan Railway Co., the Ninety-sixth street power house of the Metropolitan Street Railway Co. and Columbia College; the second party visiting the Rapid Transit Tunnel and Columbia College.

At 8.30 P. M., meeting in the Chemists' Club, Assembly Hall. Presidential address by President J. W. Richards, Ph.D.; Max Von Recklinghausen, Ph.D., demonstration of the Cooper-Hewitt lamp and rectifier.

At 10 P. M. a German-American smoker (Kneipe) will be held at the Chemists' Club, Assembly Hall, buffet, luncheon, refreshments by courtesy of the New York members. A jolly social evening is assured.

Transportation will be on the certificate plan. All members not residing in New York City should secure certificates when purchasing tickets, in order to get return at one-third rate.

The local committee consists of the following members: Dr. C. A. Doremus, chairman; Alvis von Isakovics, secretary; W. S. Cameron, assistant secretary; G. C. Adams, C. Batchelor, C. S. Bradley, Wm. Hand Browne, Jr., Dr. C. F. Chandler, E. A. Colby, Dr. F. B. Crocker, Dr. G. Drobegg, R. A. Fliess, Dr. H. Foersterling, J. C. Hatzel, Dr. N. S. Keith, E. C. Klipstein, A. A. Knudson, Dr. Morris Loeb, W. N. McCoy, C. O. Mailloux, A. Monell, E. H. Mullin, H. N. Potter, Dr. M. von Recklinghausen, E. E. Ries, Dr. S. Sheldon, N. Tesla, W. D. Weaver, E. Weston, C. E. Whitney and Dr. F. G. Wiechmann.

The above elaborate programme shows that the local committee has spared no efforts to insure a full success of the meeting. The attendance promises to be even greater than at the Philadelphia and Niagara Falls meetings.

As we already noticed in our last issue Dr. Walter Nernst, the distinguished professor of electrochemistry at the University of Goettingen and inventor of the Nernst lamp, will be present at the convention.

## CONCRETE TANKS.

By David H. Browne.

In the electrolysis of chloride solutions it is impossible to use lead-lined baths on account of the rapidity with which this metal is attacked both by soda and by chlorine. Wooden vessels are exceedingly awkward—the chlorides appearing to cause shrinkage of the fibers, in which result the hoops or bolts are readily corroded. Slate tanks are satisfactory, but are very expensive and require the utmost care in leveling up and in drawing together. As concrete has been found an efficient substitute for slate, some notes on the manufacture of concrete baths may be of interest.

The first requisite is a good, slow-setting cement. Slowness of set is necessary because in building large tanks it requires ten or twelve hours or even more to carry up the walls to the required height, and as the ramming must be continuous throughout this entire line, it is evident that if the bottom took its initial set before the sides were completed it would be injured by the vibration. The cement, therefore, should take longer to set than the tank to complete. Cheap cement is worse than useless. Saylor's cement has proved a reliable article, but any brand which will stand the "pat" test will be satisfactory.

The "pat" test is made by mixing a handful with water to a stiff paste and working the same on a glass plate into a cake about half an inch high and 3 or 4 inches in diameter. The surface should be troweled smooth and the sides brought down to a thin edge. This is allowed to stand a few hours, then is covered with a wet cloth and set aside in a cool place over night. If it sets slowly and shows no cracks on the surface or at the edges it will answer.

For the best work crushed granite should be used. This has a rough granular fracture or "bite," into which the sand and cement lock better than with any other rock. As the stone used is the weakest part, and as a good concrete, when broken, shows fracture across, and not around the particles of stone, it is important to use the best rock available. Failing granite, a trap rock or blue diorite is a good substitute. The size of the rock depends on the thickness of the walls; a safe rule being that no piece should be over one-quarter the thickness of the wall in which it is used. For ordinary tanks material passing through a screen of $1\frac{1}{2}$ inches, and over a screen of $\frac{1}{2}$ inch is satisfactory. The material smaller than $\frac{1}{2}$ inch should be rejected, as it interferes with the filling of the voids.

The solidity of concrete depends largely on the care with which these voids are filled. To determine the void space, take a pail of crushed rock, calculate the volume and find the weight. Add now water till the pail is full and weigh again. Calculate the volume of the water and simple proportion shows the empty space between the particles of rock. This space must be filled with sand, of which in turn the voids must be filled with cement. The voids of cement are in their turn filled by the water absorbed. Hence for strong concrete the common use of the formula, "4 parts rock, 2 parts sand, 1 part cement." For less careful work a larger proportion of rock is often used.

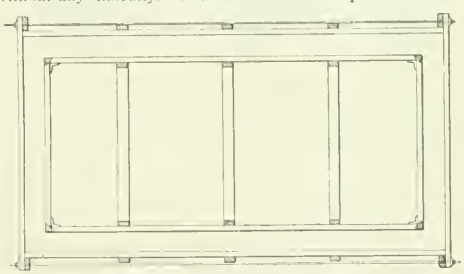
To mix the cement a tight mortar box or floor and a measure holding one cubic foot are needed. The rock should be thoroughly washed, and the sand screened from clay or gravel. One cubic foot of cement to two of sand is mixed on the dry floor to an even composition, and to this four cubic feet of stone are added, and the mass thoroughly shoveled over. Water is now added, so that, while no muddiness is apparent, each particle is moist. The mass is again shoveled over and is now ready for the mold.

This mold may be of any shape whatever. It is set on a solid floor, with a sheet of building paper underneath so that the tank does not bind to the floor. The sketch shows a form for a commercial-plating bath. The outer frame is trued at right angles and braced by struts to the floor to prevent bulging of the sides under the rammer. The concrete is now shoveled in, a few inches at a time, and thoroughly rammed until water shows at the surface. For a tank of the size shown three men are needed ramming and two men mixing and handling concrete. The tools needed are iron rammers, about 2 inches thick and 3 or 4 inches square, with a sleeve for a wooden handle. Such a tool, handled with a short, stiff blow, is better than a lighter tool, with a springy blow, the idea being simply to drive out the air from between the particles and completely fill the voids.

As soon as the bottom is of the desired thickness the inner frame is put in place and braced by cross pieces to prevent inward bulging. The sides are now rammed up, a few inches at a time. It is not desirable to lay the sides in layers, but rather to carry them up without coursing or stratification. One thing is very important, that there be no stoppages. If a meal time intervenes the men should be relieved one at a time, so that no pause occurs till the tank is completed.

The top finish is put on by bringing the concrete to within a quarter of an inch from the top of the mold and carrying this up with equal parts sand and cement troweled to a smooth surface. Any openings or holes in the tank wall are made by inserting a block of wood of the desired size in the side walls. After the tank is set the wood can be drilled or broken out.

Three or four days should elapse before the moldboards are taken down. The inner frame is removed by unscrewing the angle irons shown, when the side boards will drop inward without any difficulty. The outer form falls apart on removal



FRAME WORK FOR A CONCRETE TANK.

of the tee rods. If necessary the inner surface can be finished with a coat of sand and cement, but if planed boards were used for the molds the surface is usually quite smooth.

Concrete will not stand strong acids; caustic or chlorine has no effect upon it. A coating of paraffine or tar would help it to resist acids. It should not be subjected to sudden changes of temperature. If the heat be brought up gradually it will stand fire. It can be handled or lifted like a block of granite if ordinary care be used to prevent the tools from bearing against the sharp edges of the tank.

A tank with 6-inch bottom and 4-inch sides, containing 24 cubic feet of concrete, can be set up and completed by five men in one day. The cost decreases with the number of tanks built at one time and the facilities for handling concrete. Building four tanks of this size per day the cost per tank was as follows:

| | |
|---|---|
| Carpenter and blacksmith labor on molds..... | $1.75 |
| Concrete work labor, 30 hours @ 17½c..... | 5.20 |
| 3.5 cubic feet cement @ 60c..... | 2.10 |
| 7 cubic feet sand..... | .25 |
| 14 cubic feet crushed trap rock..... | 3.00 |
| | $12.30 |

Including finishing, taking down molds, cementing in rubber pipe connections, about $15 will cover the cost of building a tank as above described, the dimensions of which are about 3 feet wide, 6 feet long and 2 feet deep. No construction of lead, slate or wood can be made which will fulfill all the requirements of the case for this sum.

## ACETYLENE DISSOLVED IN ACETONE.

By R. S. Hutton.

Already, in 1896, Claude and Hess, in France, suggested the idea of making use of the solubility of acetylene in certain liquids as a means of storing this valuable gas. It is, however, only recently that any commercial use has been made of such a process, and much credit is due to M. Fouché, the director of the "*Cie française de l'Acétylène Dissous*," and his colleagues for the perfection of the many details necessary to make a technical application at all possible. In view of the fact that already much use is being made of this process in France, and that the Acetylene Illuminating Co., in England, is preparing to employ it extensively in a somewhat modified form, it may be of interest to give a general description of the present condition of this industry and some of its applications.

Amongst a large number of liquids which were found to dissolve acetylene very readily, acetone was chosen on account of its comparatively high boiling point (56° C.), and of its occurrence as a common industrial product. Acetone was found to dissolve 24 times its volume of acetylene at 15° C. at ordinary atmospheric pressure, and as the pressure increases the solubility also very considerably augments.

Careful experiments were carried out by Berthelot & Vielle, amongst others which showed that the solution in acetone possesses none of the dangerous explosive properties which, it will be remembered, have been ascribed to the liquefied gas. It was thus proved that the solution could be safely transported under pressure in steel cylinders similar to those used for liquefied or compressed gases. However, since the volume of the acetone increases very largely by dissolving the acetylene in it, it follows that the cylinders cannot be completely filled with the mixture, but that a space must always be left, which, of course, would be occupied by the acetylene gas at a pressure corresponding to that at which it was held in solution.

Although comparatively little danger was anticipated owing to the small volume of the free gas, and to the fact that pressures above 10 atmospheres were not to be employed, the suggestion of making use of porous materials, to fill up the whole of the space in the cylinders and to absorb the solution was warmly welcomed. The great promise of the method depends largely upon the success of this modification.

Porous bricks and specially-prepared cements have been used, possessing a low density, 0.3 to 0.5, and considerable porosity, up to 80 per cent., and these are found capable of storing the solution of the gas under pressure up to 35 atmospheres without the least fear of explosion; but such high pressures as this are not even approached in the apparatus used for commercial purposes. The cylinders employed by the French company have a capacity of 2, 12 and 100 litres, and the volume of gas stored is 10 times their volume per atmospheric pressure, and thus about 100 times their volume at the pressure of 10 atmospheres which is normally employed.

At the factory the acetylene, prepared in a properly-constructed generator and carefully dried, is compressed in a pump, the two cylinders of which, quite separate from each other, raise its pressure to 3½ and 12 atmospheres, respectively.

At this pressure it passes directly into large storage cylinders full of porous bricks saturated with acetone. The cylinders which are supplied to the public contain similar bricks and are filled from these storage vessels.

The use of acetylene in this form obviates many of the troubles adherent to the direct generation from carbide; but, of course, necessitates the use of suitable reducing valves to insure a constant pressure of gas from the charged cylinders. The loss of acetone is comparatively small, only amounting to a few per cent. in each discharge.

The applications so far made have been chiefly to the lighting of tramways, railways, and for similar purposes in which field the acetylene industry has not generally been very successful up to the present time. Much success has also been achieved by the same company with an oxy-acetylene blowpipe which has found extensive application in the welding of iron, steel and other metals. The gases are mixed in the burner in the proportions, 1 of acetylene to 1.8 of oxygen, and in order to get the velocity necessary to prevent the flame striking back, the gases are fed in under a pressure of 4 meters of water, which is, of course, easily accomplished from the cylinders of dissolved acetylene. The temperature of this oxy-acetylene blowpipe is exceedingly high, being capable of easily fusing lime, alumina, silica, etc. By regulating the proportions of the two gases either an oxidizing or a reducing flame can be obtained, but for the welding of the metals it is of course advisable to have as neutral a flame as possible by employing the gases in the proportions given above.

The further applications of this ingenious method will be followed with interest, and its influence on the carbide industry should be of the most satisfactory nature as opening up many new uses for acetylene gas.

## THE PLANT AND PROCESS OF THE INTERCOLONIAL COPPER CO.

By Woolsey McA. Johnson.

The process of the Intercolonial Copper Co. for the electrolytic coining of copper presents several features of interest to electrochemists. Numerous attempts have been made in the past to produce electrolytic copper from a copper solution by leaching ore and electrolyzing against an insoluble anode. These processes have as yet met with but little success in competition with the old processes of mechanical concentration and smelting, of chlorination roasting and cementation on scrap iron, or of direct smelting, etc., several difficulties have arisen such as when sulphuric acid is used as solvent, its destruction by the lime and magnesia in the calcined ore,

Reduction Works of Intercolonial Copper Co.

etc. The solution must be regenerated with new acid at considerable expense. Power, coal, acid, labor and electrical machinery are expensive at remote mining-centres and change economic conditions.

The insoluble anode has also been a hard question to solve. Platinum is too expensive and will lose weight with time, carbon is useless in a sulphate solution. Even the best Acheson graphite electrodes disintegrated as anodes in a sulphate solution and in almost all leaching proposition we have sulphate solutions. Lead gives the well-known "Casparische Ueberspannung" and will wear out from peroxidation just as the storage-battery positive will age with time.

How these electrometallurgical and commercial problems have been met will be found in the following account of the plant of the Intercolonial Copper Co. at Dorchester, N. B., Canada, which I inspected in January, 1903. This plant has

produced one ton of electrolytic copper daily for six or seven months, and has sold this to Canadian brass founders as equal to the best brands of electrolytic copper. Careful analysis of the cost sheet of this large experimental plant by the company's officials have convinced them that electrolytic copper can be had down at tidewater for 6 cents a pound. The working of the plant in the past year has unquestionably brought the process beyond the experimental stage. The only criterion of the successful working of any radically new process is the production of the article in large enough quantities to be sold in market. This has been done in the past year and the process has been subjected to a large scale test.

The ore of the Dorchester mines consists of a chalcocite weathered to the green carbonate or oxide. The copper is found in a vast lenticular mass in conglomerate and sandstone beds belonging to the carboniferous age. The copper ore is often associated with the fossil remains of this age and is found replacing the fossils. Large masses are found, but usually the copper in ore will run from 2 to 4 per cent. About $200,000 has been spent in blocking out ore, and the company's experts claim to have 78,000,000 tons of 3 per cent ore in sight. This claim may be right, but the geology of the copper ore is so inconstant, as to make it uncertain.

This ore would be a difficult proposition to smelt, for it does not carry enough sulphur to render direct matting practicable, nor could such low grade ore be smelted to black copper at present prices of coke and copper. Besides the ore is too silicious for furnace work. In both cases, very foul slags would result. "Weathered" chalcocite is a hard mineral to concentrate by water and large losses in tailings would ensue.

The ore could be treated by the "Henderson" process with undoubted success if a small amount of pyritic ore could be purchased, but it is doubtful if it could do better than the present process. The very small values in precious metals are

FACE OF TUNNEL, SHOWING COPPER-BEARING SEAMS.

lost by both these processes. I believe that the Henderson process has been worked with crude $Na_2HSO_4$ with good success, and this process could be made practical in this way.

Dr. N. S. Keith has a process to reduce at low red heat the copper in a carbonate or roasted ore. He mixes the ore with a small percentage of powdered coke and reduces it to small particles of metallic copper in a "Chase" roaster. The particles of metallic copper are separated easily by reason of high density by some mechanical concentrator.

Neil's $SO_2$ process is being worked successfully in Arizona. This, as is well known, consists in dissolving the copper in a solution containing an excess of $SO_2$ and precipitating it by boiling out this excess.

The Carmichael process meets the commercial conditions better than any of these for the following reasons:

1. Low lime.
2. Cheap coal, $3.65 per ton at firebox, as the plant is 4 miles from tidewater, near Nova Scotia coal mines.
3. Cheap mining.

The ore from the stopes is mined into chutes, wherever possible. These chutes lead to ore bins which empty directly into small tramcars. The cars run by gravity down the inclined tunnel and dump automatically into the ore bins before the

BATTERY OF CARMICHAEL ROASTERS.

crusher. The situation of the mine on top of hill renders tunneling practical. The ore is crushed in a Buchanan crusher and then carried by elevator to screens. The coarse from the screens goes to reducing rolls, thence back to screens, repeating the operation until the ore is 20-mesh fine. From the screens the fine ore drops to large ore bins. From the ore bins it is fed by screw conveyors into a battery of 15 Carmichael roasters. These consist of long tubes of cast iron passing through a fire-brick muffle, heated by a flame from the fire box. The first part of a roaster is a brick-lined drum. All revolve, and the ore is first partially desulphurized in brick drums. The ore next passes to the iron tube where it is dead roasted. Any lime is now sulphated and the iron is changed to the ferric state. The roasted ore from the revolving drums is carried by a chain conveyor directly to lead lined bricked vats of 20 tons capacity.

These roasters are efficient but are liable to break down, of small capacity, and a furnace man would say, cause too much "fuss and bother." Units turning out 2 to 3 tons are not in fashion in America now. The old White-Howell roaster is of similar design, but has been long given up. The ore could be more easily and cheaply roasted in a Brueckner, or, if a continuous working furnace was required, in the old-tried Brown, or the promising new roaster of Capt. Chase. There are other well known roasters that could be used if necessary, such as Davis, Pearce turret, or even hand raked reverbera tory.

The hot ore falling from the conveyor drops into a 5 per cent. solution of $H_2SO_4$. The solution of the copper takes place rapidly. This is an old and well-tried reaction that works well on a large scale. The "made solution" carrying 2.5 per cent. Cu and considerable free acid is drawn off to the "storage" vat. The fact that there is left in the solution this free acid, makes a 95 to 98 per cent. extraction a practical proposition. The tailings assay lower than 0.10 per cent. Cu. This is a strong point of the process, as the solution of the copper is slow when the copper grows high and the acid grows low.

The solution is drawn off, pumped to storage vat and impregnated with $SO_2$ gas (made by burning brimstone in an

iron pot (under blast) in the storage vat. The electrolyte runs down from the storage vat to the plating vats which are arranged in cascade. Sulphur dioxide is also blown through the electrolyte in vats by means of perforated hard rubber tubes. This bubbling of the $SO_2$ is desirable for the following reasons:

1. It makes good "top-bottom" circulation.

2. It protects lead anodes from peroxidation. Sulphation will occur in time.

3. It adds $H_2SO_4$ replacing that used in neutralizing small amounts of CaO. Practically, the acid is made at a cost of $6 per ton $H_2SO_4$—100 per cent.

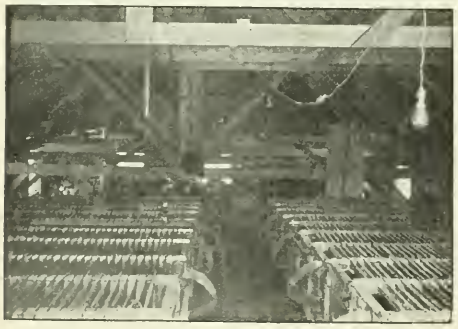
4. It acts as a depolarizer and reduces voltage of vats, and consequently amount of power necessary to deposit 1 ton of Cu.

This part of the process is old, in fact first patented in 1878 by an Englishman. It has been repatented several times in many countries, although it is quite doubtful if the Chinese or Fiji Island patents are valid. I worked out this electrochemical reaction independently some years ago, as follows:

$$4\,(+) + \overline{\overline{SO_2}} + \overline{\overline{O}} + H_2O = \overset{++}{H_2} + \overline{\overline{SO_4}} + 2\,(+)$$

where the + and — in paranthesis and the + and — over the chemical symbols represent ionic charges.

This reaction with lead or platinized platinum anodes proceeds in accordance with Faraday's law. As there is a union



ELECTROLYTIC ROOM.

of positive and negative charges, the free energy necessary for electrolysis is less than if no $SO_2$ were present. In other words the $SO_2$ acts as a depolarizer. My idea had been to use this for $H_2SO_4$ production in connection with an electrolytic refining plant which was proposed by my employer. This idea is, of course, also old. It is merely mentioned as one more illustration of the fact that different minds often produce the same solution of problems. The last man to re-invent this reaction is C. J. Tossizza, of Paris, who patented it in the United States, September 30, 1902.

The copper is precipitated at the Intercolonial plant at 1.5 volts, 6 ampères per square foot, electrodes of lead about 1½ inches apart. The current efficiency is about 90 per cent. The cathodes are greased and graphitized. The cost of power would be from $25 to $30 in the present small generating plant. This is more than cost of "cementing" on scrap iron, but the product is worth at least $30 per ton more than 80 per cent. "cement copper." Besides the solution is easier in this process, because the copper can be thrown down from acid solution, while in the "cementation" process free acid means just so much more iron used before the copper is thrown down.

Using wood at $1 a cord, or coal at $4 a ton in "Loomis-Pettibone" gas producers with Westinghouse gas engines to generate power, as is done by Phelps, Dodge & Co., in Mexico and Arizona, the cost would be much lower, probably as low as $8 to $9. Water-power might reduce the cost of power to $5 or even $2, as a low figure.

The electrolysis is conducted until the Cu content is reduced from 2.50 per cent. to 1.00 per cent. The solution regenerated in acid by anode and cathode reaction is not subjected to further electrolysis, but is used for leaching new ore. This is another skillful use of electrochemical knowledge, as the removal of the last 1 per cent. of Cu would be very expensive, because of decreased current efficiency.

The ore when leached is washed and sluiced by water from the mine which is on a higher level than the electrolytic plant.

This process is a good verification of the prophecy made by the English electrochemist, Mr. Bertram Blount, on page 88 of his "Practical Electrochemistry:" "That it (electrolytic winning of copper) will be achieved in the near future is probable enough. . . . What is wanted is not so much a totally new device as a well-schemed plant embodying perhaps nothing but what is common knowledge, but planned so as to be fairly permanent as a whole and with its perishable parts easily and cheaply renewable."

The estimate of the company is as follows:

| | | |
|---|---|---|
| Value of 57 pounds of copper at 12 cents per pound, | | $6.84 |
| Cost of mining and delivery to mill, per ton | $1.50 | |
| Cost of milling, per ton | 2.00 | |
| | | 3.50 |
| Net profit, per ton | | $3.34 |

"These figures, based upon a comparatively small tonnage, bear out closely the early estimates of Prof. Carmichael on the cost of producing copper here, and are believed to be conservative. It is therefore apparent that the plant as at present constructed, running to its full capacity, will show substantial earnings on the capital stock issued, while it is obvious that the operation of a large plant treating 1,000 tons daily, for which the ore supply is believed by our engineers to be ample for a long term of years, will establish this enterprise as a great and permanent mining industry.

"The mining and development work of the company has been under the supervision of L. S. Griswold, M. E., of Boston. The process for treating the ore and the plant are the design of Prof. Henry Carmichael, of Boston."

If the plant and process do not develop into a commercial-paying proposition it will be in my opinion either because 3 per cent. ore cannot be found or because the lime and other soluble impurities increase to too high a figure, or because of unexpected financial trouble. The process is certainly well suited to treat ore of this character. Low copper, high lime, or lack of capital would of course cause a failure.

---

Output of Electrolytic Refineries.—Mr. Titus Ulke kindly informs us that since he sent us his article "Notes on the History of Electrolytic Copper Refining in America," published in our last issue, he has received subsequent returns from several refineries, which change somewhat the statistical figures given in his article. The corrected figures are as follows: The total daily copper output is 764 tons, or 279,000 tons per year. At the same time the amount of silver and gold recovered per year in the electrolytic copper refineries is 27,000,000 ounces of silver and 346,020 ounces of gold.

---

From reports of the Treasury Bureau of Statistics it appears that the copper exports of the United States consist chiefly of electrolytic copper. Their value was $33,534,899 in 1901, and $45,485,598 in 1902. The number of electrolytic copper-refining plants in the world, either now in active operation or ready to start operation, is 33, of which 10 are in the United States, 9 in Germany, 6 in Great Britain, 4 in France, 2 in Austria and 2 in Russia.

## THE ELECTRIC REDUCTION OF IRON ORES AND THE CONVERSION OF IRON INTO STEEL IN AN ELECTRIC FURNACE.

By Louis Simpson.

When Sir Henry Bessemer first brought his invention before the notice of the steel manufacturers of Great Britain, both he, and his invention, did not receive, at their hands, the attention and consideration that has since been proved the invention warranted.

It was only when enterprising capitalists advanced the money necessary to operate a works, wherein steel was manufactured under what is now known as the Bessemer process, that the steel makers of Great Britain began to investigate the process, and eventually applied for licenses for rights to manufacture.

History is ever repeating itself. It is not surprising that the steel makers of to-day have looked with scepticism upon all of the several processes now available, of electric reduction and conversion, although certain of those processes have reached practical development and are here to stay.

One cause of their want of interest is probably due to the fact that, in the past, the advocates of the electric furnace have not shown unanimity in advancing the best claims of this process and have at times claimed that which could not be sustained. They have too often so spoken and written as to raise doubts in the minds of practical steel manufacturers, even in some instances to the extent of "damning by faint praise." At the Niagara Falls meeting of the Electrochemical Society, Mr. Salom stated that in his opinion: "There is not much danger, in the immediate future, of the electric furnace superseding the blast furnace, as a method of manufacturing iron or steel, *although the possibilities of it are not to be ignored in the future.*" This remark would suggest the thought that whilst the steel manufacturer may for the present ignore the possibilities of the electric process, yet it would be well for him to give it attention, lest some fine morning he might wake up to find that, whilst resting in fancied security, some competitor had captured part of his business by the aid of the electrical process. Other speakers expressed the opinion that the electric furnace for iron and steel "has the very great handicap of high cost." The report published in The Electrochemical Industry is herein quoted. It is, however, not clear whether the "high cost" referred to is intended to mean a supposed high cost of working or to a supposed high first cost of erecting a furnace.

Mr. E. R. Taylor, at the same meeting, claims that "he could now construct a continuous electric furnace that would dwarf the largest blast furnace in existence." Mr. Taylor has been very successful with his furnace, which he uses for the manufacture of carbon bi-sulphide, and there would seem to be no reason why the same furnace with modifications should not be used for the reduction of iron ores. But for the fact that Mr. Taylor's electrical plant is of insufficient capacity, his type of furnace, long ago, would have been tested as to its possibilities in the reduction of iron ores. In The Electrochemical Industry's issue of February, Mr. Marcus Ruthenburg claims that through a furnace of his invention "iron ore can be reduced at a cost of 500 kilowatt hours per ton."

Few of those who have written on this question have published statements that would appeal to the practical manufacturers, that is to say, those who have made it their business to know something about the cost of power production, of electricity and of steel making.

Some of these writers even lessen the value of their opinions upon the possibilities of the electric furnace, by making statements upon some side issue, which statements being obviously open to criticism, causes the reader to doubt the correctness of the opinions and data given in respect to the electric furnace.

The commercial practicability of the electric process is a question of such a complex character that it is difficult for an expert of any one of the several branches of science interested to form a correct judgment upon the question, as a whole; unless he is posted in all the other branches, and further, unless he has considerable knowledge of the commercial end of the question. It is not sufficient that this question should be considered by an electrochemist, nor by an hydraulic, civil, mechanical or electrical engineer; it is not sufficient that it should be considered by a metallurgist. It is necessary that the question should be considered by a man of experience in the market for which the steel made by the electric process is intended.

To illustrate this Mr. James Swinburne, president of the Institute of Electrical Engineers in Great Britain, in his presidential address given before that Institute, stated as his opinion that water-powers were of no great commercial value. The fact so stated may be and probably is correct, if applied to Great Britain, but is not correct when applied to the continent of North America, and especially to the Dominion of Canada. The causes given by Mr. Swinburne as being the basis for his statement are not existent at or around a considerable number of the waterfalls of this continent. Had Mr. Swinburne been an hydraulic engineer, had he the information, and had his experience in hydraulic propositions equalled his experience as an electrical engineer, he would either not have made such a statement or else he would have been careful to have limited its application to certain European countries.

It is not necessary to claim that the electric furnace will supplant the blast furnace or cause a revolution in the manufacture of steel. The blast furnace will probably be used under certain conditions. The electric furnace will certainly be used when and where other conditions exist. Amongst these conditions, the proximity of the consuming market to the electric furnace is of an importance too great to be ignored.

It is now admitted that the quality of steel made through the electric furnace is equal, and it is a question if it is not superior to the steel produced by any other known process. The question at interest is whether it is possible to manufacture steel using the electric furnace at a less cost, or at the same price as can be done by other methods. To the cost of producing steel must be added any extra freight, over and above the average, which may have to be paid for conveying the steel from the steel works to the different consuming markets.

Of course, the cost of carbon, in whatever form used, and of electrical power, if used in place of carbon, is a considerable factor. It cannot, however, be claimed as being the only factor worthy of consideration.

It is always difficult to compare the cost of producing manufactured materials or goods, when the conditions, under which they are manufactured, differ widely. There is difficulty in ascertaining the lowest cost of producing steel by the blast and open-hearth furnace process. Up to date, although numerous small works are producing steel of good quality by the electric process, no works have been erected of a magnitude sufficient or under such favorable natural and local conditions, as would insure the most economical production. It would, however, be no argument to assert that steel cannot be produced at a certain low figure, because under the conditions existing at and around these several small plants, steel by the electric process is not being produced at a cost as low as it can be produced elsewhere under different conditions.

Certain data have been secured from the results obtained at certain of these works, which have produced steel of excellent quality. This steel has not been produced under the most favorable conditions, such conditions as are known to exist upon this continent, more especially in the Dominion of Canada. This data corrected to conform with the conditions indicated will give the possible cost of producing steel by the electric furnace where conditions are favorable.

The charges which together make up the cost of steel are as follows:

1 Raw material, consisting of (*a*) iron ore (assembled).
(*b*) Carbon (assembled), used to combine with the oxygen contained in the ores.
Carbon (assembled), used for heating or electric power used for heat.
(*c*) Limestone (assembled).
2 Labor
3 Repairs, renewals, taxes, insurance and depreciation.

To which must be added any excess of freight charges which have to be paid by the customer above the lowest existent freight charges.

The lowest known cost of producing steel ingots per ton by the blast and open hearth furnaces, have been stated to be as follows: It must, however, be remembered that the works were situated at a considerable distance from the chief consuming markets, therefore an unknown sum for excessive freight charges has to be added.

| | | |
|---|---|---|
| 1 | Iron ores (assembled) | $2.33 |
| | Loss in iron from pig to steel | 1.00 |
| | | $3.33 |
| | Coke | 3.77 |
| | Limestone | .30 |
| 2 | Labor | 2.50 |
| 3 | Renewals, repairs, depreciation, etc | 2.00 |
| | Extra freight | uncertain |
| | Cost of steel ingots at works, to which must be added cost of extra freight to consuming markets | $11.90 |

To-day the costs of iron ores, coke and labor have all advanced. At Pittsburg the cost of these items is considerably higher than quoted above, but the cost of excessive freight charges would in the latter case be unimportant. This question of excess in freight charges must always be borne in mind, but cannot be stated at any constant figure, it being ever a varying quantity.

Under conditions known to exist upon this Continent, more especially in the Dominion of Canada, the cost of iron ore and of limestone (assembled) as above stated may be considerably reduced, while the cost of labor is lower, as also the cost of repairs, renewals, depreciation, etc., when the electric furnace is used. For the local markets there would be a very considerable saving in the freight charges paid by the consumer. The total of these savings, in one case now under consideration would amount to over $3.50 per ton.

The lowest known cost of the carbon used in the blast and open-hearth furnaces, has been given as $3.77 per ton of steel ingots, this cost, however, cannot to-day be duplicated. The saving of $3.50 already indicated would permit the steel maker, when using the electric process, to expend upon the carbon, electric power and electrodes, the sum of $7.27 for each ton of steel ingots made, and yet the total cost would not exceed the lowest cost of production, under the blast and open-hearth furnace process.

According to data in the possession of the writer, steel ingots can be made by the electric furnace at a cost as low as $10.61 per ton, while the inventors of certain new electric furnaces, not yet tested practically, claim reductions in the cost of the process made in reducing the amount of electric power and of electrodes consumed, which, if correct would, in one case, amount to a reduction of $2.09 per ton, and in the other, to a reduction of 81 cents per ton, making the cost price $8.52 and $9.80 per ton, respectively.

There has always been great contention as to the cost of electric power. Calculations of cost have been based upon power costing $20 per horse-power year, because forsooth, that is the price charged by the power company at Niagara Other calculations have been based upon power at $15 per horse-power year, because another power company charges such an annual rental, while other calculations have been based upon the more reasonable rental of $10 per horse-power year, but for a reason no better than that possessed by those who used $20 per year, as a basis for their calculation. One expert condemns employing hydraulic power wherewith to generate electric power, and claims that electricity can be generated from the combustion of soft coal at a price that will put "water-power in the shade." This expert claims that 500 kilowatt hours can be produced by the combustion, *under a steam boiler*, of 1,000 pounds of soft coal.

It is unnecessary to point out that up to date it has been impossible, *under ordinary continuous working condition*, to produce 500 kilowatt hours by the consumption of 1,000 pounds of any kind or quality of coal, burned under any kind of steam boiler. Nor is the quantity of coal consumed by any means the sole expense in producing steam, by the combustion of coal. Wages, repairs, oil, depreciation, insurance, packing, etc., must be accounted for.

When a power company leases electric power at the rate of $10 per annum, such rental is not necessarily the cost of producing electric power. In most, if not in all of these power companies there is more water than that which flows or has gone over their water falls, and in any case the annual rental not only includes the cost of operating, of maintenance and of depreciation (the actual cost of the power), but also an amount necessary to provide for interest upon a large bond issue and further the dividends to be paid upon a large issue of stock, much of which is made necessary by the presence in their stock of the water, that never went over the falls.

Under favorable conditions electric power can be produced for less than $4 per electric horse-power per year.

There are certain important advantages which may be claimed for the electric process over the blast and open hearth furnace process They are as follows:

1. The steel produced is more compact, it is more regular in quality.

2. In the same works, and that of no great magnitude, different qualities of steel and of steel alloys can be produced and that at a minimum cost.
